INTRODUCTION

Pathogenic bacteria have to overcome various types of stress as they colonize their hosts. Understanding how the stress response operates in such bacteria is important from the overall perspective of bacterial pathogenesis. Stress-response pathways are highly complex and involve multiple factors. Many of these factors belong to the chaperone category of proteins. It is believed that high-level expression of chaperone proteins under stress conditions is necessary for preventing irreversible loss of protein function (Lindquist & Craig, 1988).

A substantial amount of information regarding stress tolerance pathways is available in the case of *Escherichia coli*, where it has been shown that the regulation is positively controlled by heat-shock sigma factors σ^32^ (Bukau, 1993; Georgopoulos et al., 1994; Yura et al., 1993) and σ^E^ (Raina et al., 1995; Rouviere et al., 1995). Stress genes may also be negatively controlled by repressors. One such repressor, HrcA, which binds to a DNA sequence named CIRCE (controlling inverted repeat of chaperone expression) (Babst et al., 1996; Bahl et al., 1995; Schulz & Schumann, 1996; Segal & Ron, 1996; Zuber & Schumann, 1994), is the most widespread and controls the expression of *dnaK* and *groE* operons in several Gram-positive bacteria. Another well-known regulator is HspR, which binds to a sequence known as HAIR (HspR-associated inverted repeats) (Grandvalet et al., 1999). In *Mycobacterium tuberculosis*, HspR is expressed from the *dnaK-grpE-dnaJ-hspR* operon. HspR has been demonstrated to act as a repressor of this operon. Subsequent evidence has indicated that the expression of not only the *dnaKJE* genes, but also several other genes of *M. tuberculosis*, is repressed by HspR. One of these, *acr2*, encodes an α-crystallin family protein which appears to be linked to virulence/pathogenesis (Stewart et al., 2005; Wilkinson et al., 2005). HspR in itself may be a virulence factor, since its knockout resulted in loss of persistence (Stewart et al., 2003). The mechanism by which this happens is not known in detail but it has been suggested that in *hspR* mutants, chaperones such as DnaK, which are highly antigenic, are overexpressed and this results in a better immune response in the host. However, since HspR controls several other virulence-related genes such as *acr2* (Stewart et al., 2002), the overall mechanism of HspR action could be more complex than is presently thought. Binding of mycobacterial HspR to HAIR has been demonstrated using *in vitro* renatured protein (Stewart et al., 2001). However, this binding was not heat sensitive. It has been suggested that...
the presence of other factors could play a role in conferring heat sensitivity. In later studies, using a similar protein from Streptomyces coelicolor (Buca et al., 2000, 2003), it was shown that DnaK acts as a co-repressor for HspR. Both these observations indicate that the activity of HspR-like regulators is possibly controlled by multiple factors, one of which is certainly DnaK.

Given the importance of HspR in regulating stress responses as well as virulence-related genes in M. tuberculosis, its DNA-binding activity was investigated with particular focus on the involvement of chaperones such as DnaK and GroEL in the process. The results show that whereas DnaK does indeed act as a co-repressor, as reported earlier (Buca et al., 2000, 2003), its activity is positively modulated by GroEL and DnaJ, and negatively by GrpE.

METHODS

Bacterial strains and plasmids. E. coli strain XL1 Blue was used for routine manipulation of plasmid DNA (Sambrook et al., 1989). Mycobacterial DnaK was purified after expression from plasmid pMRL6. dnak/RV0350 (acquired through ‘TB Research Materials & Vaccine Testing’, NIH, NIAID, based at Colorado State University) in E. coli BL21(DE3). Strains expressing mycobacterial GroELs 1 and 2 were obtained as gifts from Dr Sekhar Mande, CDFD, Hyderabad, India.

Construction of expression plasmid. The M. tuberculosis HspR expression plasmid pTD-R30 was constructed by cloning the PCR-amplified 381 bp fragment of the hspR gene (RV0353) at the BamHI-HindIII site of pQE30 (Qiagen), using mycobacterial genomic DNA as template and 5'-CGGGATCCATGGCGAAGAACCC-3' and 5'-CCCAAGCTTTCACCGGCGCGGTTT-3' as forward and reverse primers, respectively. The protein expressed from the recombinant plasmid contains a stretch of six histidine residues at the N-terminus. Clones expressing M. tuberculosis DnaJ (RV0352) and GrpE (RV0351) were constructed in the same way by cloning the respective PCR amplicons in the expression vector pQE30.

Chemicals. Chromatography material (Ni²⁺-NTA agarose), was purchased from Qiagen. ATP-γS was purchased from Calbiochem. Other chemicals for protein expression, purification and analysis were of the highest purity grade, obtained from SRL Laboratories, India. Chaperones at specified concentrations, followed by the addition of salmon sperm DNA and then the bands were visualized by autoradiography. In the case of GroEL1, the non-ionic detergent Triton X-100 was omitted or replaced by the non-hydrolysable analogue ATP-γS. Renaturation was done in either the absence or presence of the chaperones for 1 h. After this time, aliquots (25 μl) were removed and added to the DNA-binding assays. All DNA-binding assays were performed in a final volume of 30 μl. After 5 min pre-incubation in the presence of salmon sperm DNA, probe binding was done for 15 min as mentioned above. Binding was then monitored by EMSA. For a kinetic analysis, the refolding period was divided into four time intervals of 15 min each.

RESULTS

Involvement of chaperones in the activation of HspR

The ability of GroEL and/or DnaK to stimulate the activity of the in-column renatured protein was tested. The results

...
show that, as expected, HspR did not give any binding on its own, but in the presence of the co-repressor DnaK, binding was observed (Fig. 1a). That the observed binding did not arise out of direct interaction of DnaK with the target was confirmed by performing a control experiment in which HspR was omitted (Fig. 1b, lanes 1 and 2). In contrast to DnaK, no stimulatory effect was encountered in the case of either of the mycobacterial GroELs, GroEL1 and GroEL2 (Fig. 1c and d, respectively). In order to investigate whether these GroELs play a role in the activation process in the presence of DnaK, a binding assay was set up in which the HspR concentration was lowered fourfold relative to that used in Fig. 1a and the DnaK concentration was kept at the lowest level. Under these conditions, neither HspR nor the DnaK-HspR combination showed any binding (Fig. 1e, lanes 2 and 6). GroEL1 and GroEL2 were then added either under refolding conditions (in the presence of ATP and pre-incubation in the presence of chaperones for 1 h) or directly into the binding assay. The results (Fig. 1e, lanes 3, 4, 7 and 8) show significant stimulation by both the GroELs irrespective of the manner in which they were used. GroEL requirement, however, appeared to be essential only under limiting conditions. This was evident from the activity observed using a higher concentration of HspR (Fig. 1e, lanes 10–12). In this case, no additional stimulatory effect was observed with the GroELs over and above that obtained in the presence of DnaK.

**Refolding denatured HspR**

The next question addressed was whether the mycobacterial GroELs have any role to play in the activation of the heat-denatured protein. HspR (1 μg) was heated at 42 °C for 15 min and then refolded in the presence of 0.5 mM ATP, DnaK (10 μg) and increasing amounts of GroEL1. The results of this experiment (Fig. 2a) showed that the presence of GroEL1 aided the refolding of heat-denatured HspR in a dose-dependent manner. Maximum activity was encountered when the molar ratio between DnaK and GroEL1 was approximately 1:1. The reactivation kinetics of heat-treated HspR was then investigated either with DnaK alone or with DnaK in the presence of GroEL1 or GroEL2. The results showed that within the stipulated time of 1 h, DnaK failed to reactivate HspR, but in the presence of either of the GroELs, a time-dependent increase in activity was observed (Fig. 2b, lanes 5–8 and 9–12). These results confirm that the presence of GroEL is essential for efficient refolding of HspR.

**ATP requirement for reactivation of HspR**

To test the requirement for ATP, either chemically or heat-denatured HspR (Fig. 3a and b, respectively) was allowed to refold in the presence of DnaK alone or in combination with one of the two GroELs. Activity of the refolded protein was then judged by binding assays. The results showed that in the absence of chaperones there was little or no activity (Fig. 3a and b, lanes 1). If refactored in the presence of DnaK alone, a low level of reactivation was observed, particularly in the case of the heat-denatured

Fig. 1. Stimulation of HAIR-binding activity of in-column renatured HspR by the chaperones DnaK, GroEL1 and GroEL2 either individually or in specific combinations. (a) Binding assays were performed using 1 μg HspR and increasing amounts of DnaK (2.5, 5 and 7.5 μg) in a final reaction volume of 30 μl. (b) Binding activity in the presence of either DnaK alone (5 and 7.5 μg) or DnaK (5 and 7.5 μg) + HspR (1 μg). (c, d) Binding activity in the presence of increasing amounts (2.5, 5, 7 μg, lanes 2–4) of GroEL1 and GroEL2, respectively, in the absence of DnaK. Lane 1 shows binding in the presence of DnaK (5 μg) but no GroEL. (e) Stimulation of the binding activity of HspR (0.25 μg used in lanes 1–8, or 1 μg in lanes 9–12) by DnaK (2.5 μg) and GroEL1 and GroEL2 (2.5 μg each). In lanes 1–4, the chaperones were added in a 1 h pre-incubation step in a refolding buffer, which contained 0.5 mM ATP, whereas in lanes 5–12, the chaperones were added directly into the EMSA. In each case ‘F’ denotes mobility of the free probe.
protein (Fig. 3b, lane 2). This low level of DnaK-mediated reactivation was ATP dependent (Fig. 3b, lane 2 compared to lane 3). The level of reactivation was, however, markedly increased in the presence of either DnaK (10 μg) alone, or DnaK and increasing amounts of GroEL1, as indicated. The final reaction volume in the refolding process was 100 μl. After incubation for 1 h, 25 μl aliquots were withdrawn and added to binding assays. (b) Kinetic analysis was performed in the same way as in (a) except that the incubation period under refolding conditions was increased in a stepwise manner from 15 min to 1 h as indicated. In all cases the binding assays were done for 15 min.

![Graphs showing dose-dependent activation of heat-denatured HspR and kinetic analysis](http://mic.sgmjournals.org)

**Fig. 2.** (a) Dose-dependent activation of heat-denatured HspR. In-column renatured HspR (1 μg) was denatured at 42 °C for 15 min, followed by incubation under refolding conditions in the presence of either DnaK (10 μg) alone, or DnaK and increasing amounts of GroEL1, as indicated. The final reaction volume in the refolding process was 100 μl. After incubation for 1 h, 25 μl aliquots were withdrawn and added to binding assays. (b) Kinetic analysis was performed in the same way as in (a) except that the incubation period under refolding conditions was increased in a stepwise manner from 15 min to 1 h as indicated. In all cases the binding assays were done for 15 min.

**DISCUSSION**

Stress response can play a major role in the survival of intracellular pathogens such as *M. tuberculosis* in various ways: (a) such a response can protect the bacteria within the hostile environments of the host, thereby allowing them to grow rapidly; (b) the stress proteins may themselves contribute to pathogenesis; and (c) many stress proteins, being immunogenic, contribute to the generation of host immunity. A stress response induced in a bacterium during its invasive cycle may therefore act as a double-edged sword that can prove to be both beneficial as well as harmful.

Previous investigations into mycobacterial HspR appear to be limited to two studies (Stewart *et al.*, 2001, 2002) where the consequences of the deletion of *hspR* were examined. Some idea about how mycobacterial HspR might function may be gathered from an investigation done on a similar protein from *S. coelicolor* (Bucca *et al.*, 2000, 2003). One of the points made categorically in the case of *S. coelicolor* was that DnaK is capable of acting as a co-repressor in HspR-mediated binding to the operator DNA sequence known as HAIR.

In the present study, it was shown that, as in the case of the *S. coelicolor* HspR, in this case too, DnaK acts as a co-repressor. However, the novel aspect presented here is the stimulatory role of the GroEL class chaperones of *M. tuberculosis*, GroEL1 and GroEL2, in the process. It could be demonstrated that whereas the presence of DnaK was necessary, it was not sufficient for HspR activation. The mycobacterial GroELs, GroEL1 and 2, had a major role to

**Role of the co-chaperones of DnaK**

The effect of mycobacterial DnaK co-chaperones DnaJ and GrpE on DnaK-dependent reactivation of HspR activity was investigated. Addition of DnaJ along with DnaK during renaturation resulted in activation of HspR in a manner similar to that observed with GroEL (Fig. 4a, lanes 6–9 compared to 2–5). It may be added that, in the absence of DnaK, DnaJ did not stimulate HspR activity (data not shown). Addition of GrpE to the refolding mixture did not show any stimulation. In fact, there were indications that the presence of GrpE was inhibitory. To obtain a clear idea of the extent of inhibition, a renaturation experiment was performed in which GrpE was present along with DnaK. In this assay the amount of HspR was doubled, so that the initial binding activity was strong enough to allow detection of inhibition by GrpE. The results showed that when HspR was renatured in the presence of GrpE, its DnaK-dependent binding activity decreased sharply (Fig. 4b, lanes 2–5 compared to 1). This indicated that GrpE inhibits the DNA-binding capacity of the DnaK–HspR combination.
play in the activation processes. This co-stimulatory role of the GroELs was particularly evident when limiting amounts of HspR were used. ATP also seems to play a role, particularly in cases where the completely denatured HspR protein was refolded. Specifically, ATP hydrolysis appears to be a key event since the non-hydrolysable counterpart failed to support activation. There appears to be a degree of redundancy in the choice of co-chaperones, since DnaJ was found to be as effective as GroEL. Although the end result is the same, it is most likely that GroEL and DnaJ assist DnaK through different mechanisms. GroEL is generally known to act as a ‘cage’ within which a protein can fold efficiently (Mayhew et al., 1996), whereas DnaJ is known to facilitate interactions between DnaK and its substrates (Liberek et al., 1995). The positive role played by DnaJ is on expected lines but the inhibitory effect of GrpE was unexpected. GrpE is considered to be a nucleotide exchange factor that replaces DnaK-bound ADP with ATP (Brehmer et al., 2004). ATP-bound DnaK has lower affinity for the substrate compared to the ADP-bound protein and therefore exchange of ADP with ATP by GrpE could possibly result in the release of HspR, although this has not been specifically verified. Nevertheless, this result suggests that following its successful folding, HspR must continue to be associated with DnaK in order to be active. That DnaK is indeed retained in the final DNA–protein complex was demonstrated by the antibody supershift experiment. The GroELs do not seem to be part of the

![Fig. 3.](image_url)
complex. No specific supershift was observed with the respective antiserum although their titres and specificities were comparable to that of anti-DnaK serum.

The observations presented are novel, since in the case of S. coelicolor HspR, activation depended solely on DnaK: neither GroEL nor ATP nor its co-chaperones had any role to play (Bucca et al., 2000, 2003). The differences in observations could be due to the simple fact that these proteins are after all derived from different systems. Alternatively, it could be due to the fact that in the previous study with the S. coelicor HspR, the DnaK and GroELs used were from the unrelated bacterium E. coli, whereas in this study all the proteins used were derived from the same system, M. tuberculosis. However, the most likely reason appears to be the concentrations used. As this study shows, the stimulatory effect of the GroELs was discernible only when the HspR-binding activity was maintained at a suboptimal level.

How the mycobacterial GroELs, GroEL1 and GroEL2, assist DnaK is not clear. As mentioned earlier, GroELs are generally known to act as cages for protein folding (Mayhew et al., 1996). A complex cycle of ATP-dependent events ensures that an unfolded protein is captured and released as a completely or partly folded protein. Most of the information regarding GroEL function is derived from studies using E. coli GroEL. The role of mycobacterial GroELs in promoting protein folding in general is still not clearly understood. It has been observed that these GroELs do not require either ATP or GroES to promote protein folding (Goyal et al., 2006). Hence, in this particular scenario the ATP dependence is unlikely to be due to the GroELs; rather it is most likely that it is DnaK that utilizes the ATP. That this is possibly the case is evident from the observation that, in some of the experiments where HspR activity was limiting, DnaK alone could activate HspR, albeit at a low level, in an ATP-dependent manner.

Since the present set of experiments strongly suggests a role for protein folding, the question may be raised as to how this phenomenon is relevant in the cellular context. To find a rationale it must be taken into account that HspR is a regulator of the heat-shock response. In response to heat or equivalent stress, HspR is expected to be denatured and released from the HAIR operator. However, the cell must get back quickly to its ground state. For this, HspR must attain its native structure as soon as possible, and in this context the presence of GroEL along with DnaK could be an important factor. Whether this control has anything to do with pathogenesis is a matter of conjecture, but since several virulence genes are regulated by HspR (Stewart et al., 2002), some relationship with pathogenesis is likely to emerge in the future.

ACKNOWLEDGEMENTS

We thank Dr Sekhar Mande for the two plasmids expressing the GroELs. We also thank P. Halder for technical assistance. T. D. G. is grateful to UGC, Govt of India, for her fellowship. The work was partly funded by DBT, Govt of India.
