Nutrient acquisition by mycobacteria

Michael Niederweis

Department of Microbiology, University of Alabama at Birmingham, 609 Bevill Biomedical Research Building, 845 19th Street South, Birmingham, AL 35294, USA

The growth and nutritional requirements of mycobacteria have been intensively studied since the discovery of Mycobacterium tuberculosis more than a century ago. However, the identity of many transporters for essential nutrients of M. tuberculosis and other mycobacteria is still unknown despite a wealth of genomic data and the availability of sophisticated genetic tools. Recently, considerable progress has been made in recognizing that two lipid permeability barriers have to be overcome in order for a nutrient molecule to reach the cytoplasm of mycobacteria. Uptake processes are discussed by comparing M. tuberculosis with Mycobacterium smegmatis. For example, M. tuberculosis has only five recognizable carbohydrate transporters in the inner membrane, while M. smegmatis has 28 such transporters at its disposal. The specificities of inner-membrane transporters for sulfate, phosphate and some amino acids have been determined. Outer-membrane channel proteins in both organisms are thought to contribute to nutrient uptake. In particular, the Msp porins have been shown to be required for uptake of carbohydrates, amino acids and phosphate by M. smegmatis. The set of porins also appears to be different for M. tuberculosis and M. smegmatis. These differences likely reflect the lifestyles of these mycobacteria and the availability of nutrients in their natural habitats: the soil and the human body. The comprehensive identification and the biochemical and structural characterization of the nutrient transporters of M. tuberculosis will not only promote our understanding of the physiology of this important human pathogen, but might also be exploited to improve tuberculosis chemotherapy.

Introduction

The growth and nutritional requirements of mycobacteria have been intensively studied since the discovery of Mycobacterium tuberculosis (Koch, 1882). These studies have resulted in an overwhelming body of literature on the physiology of mycobacterial metabolism in the years before the dawn of molecular biology (Edson, 1951; Ramakrishnan et al., 1972; Ratledge, 1982). For example, the utilization of many solutes such as carbohydrates, alcohols, carboxy acids, fatty acids and amino acids by mycobacteria was examined by measuring oxygen consumption (Edson, 1951). It is striking that the identity of many transporters for essential nutrients of M. tuberculosis and other mycobacteria is still unknown despite considerable progress in the development of genetic methods for mycobacteria (Kana & Mizrahi, 2004; Machowski et al., 2005). Recently, in particular carbon metabolism of mycobacteria has attracted renewed interest since the observation that M. tuberculosis relies on the glyoxylate cycle for survival in mice (McKinney et al., 2000; Munoz-Elias & McKinney, 2005). This indicates that M. tuberculosis uses lipids as the main carbon source during infection. On the other hand, genes that encode a putative disaccharide transporter were found to be essential for M. tuberculosis during the first week of infection (Sassetti & Rubin, 2003), indicating that M. tuberculosis may switch its main carbon source from carbohydrates to lipids with the onset of the adaptive immune response. Obviously, this requires that M. tuberculosis has the capacity to take up these particular carbohydrates and lipids. However, both the carbon sources and the corresponding uptake proteins are unknown for M. tuberculosis inside the human host. Surprisingly little is known about the identity and properties of many other transporters for essential nutrients, even for in vitro-grown M. tuberculosis or for Mycobacterium smegmatis, which is often used as a fast-growing, non-pathogenic model organism. However, recent progress has been made in understanding the uptake of some nutrients in both M. smegmatis and M. tuberculosis. For example, proteins have been identified and characterized that are involved in uptake of several nutrients such as phosphate (Gebhard et al., 2006; Peirs et al., 2005; Vyas et al., 2003; Webb, 2003; Wolschendorf et al., 2007), sulfate (Wooff et al., 2002) and some amino acids (Seth & Connell, 2000; Talaue et al., 2006). This review focuses primarily on the uptake of solutes that are considered to be major nutrients for mycobacteria. The
The cell envelope of mycobacteria

Permeability barriers in mycobacterial cell envelopes

Nutrient uptake mechanisms obviously depend on the permeability barriers imposed by the cell envelope. Therefore, it is necessary to review the current status of the research about the cell envelope of mycobacteria. The terms are defined as follows (Beveridge, 1993; Beveridge & Kadurugamuwa, 1996; Graham et al., 1991): The cell wall consists of the periplasm, the peptidoglycan layer and, for Gram-negative bacteria, the outer membrane. The periplasmic space represents an extracytoplasmic compartment confined between the plasma membrane and an outer structure (outer membrane versus a peptidoglycan–teichoic acid–protein network for Gram-negative and Gram-positive bacteria, respectively). The periplasm is composed mostly of soluble components. The cell envelope comprises the inner membrane and the cell wall. The components of the cell envelopes of both Gram-positive and Gram-negative bacteria have recently been visualized by cryo-electron microscopy (Matias et al., 2003; Matias & Beveridge, 2005, 2006).

In microbiology textbooks, mycobacteria are still classified as Gram-positive bacteria. However, it is well documented that mycobacteria, unlike other Gram-positive bacteria, have evolved a very complex cell wall, comprising an arabinogalactan–peptidoglycan polymer with covalently bound mycolic acids of considerable size (up to 90 carbon atoms), a large variety of extractable lipids (Barry et al., 1998; Daffe & Draper, 1998) and pore-forming proteins (Niederweis, 2003). Most of the mycobacterial lipids are constituents of the cell envelope, which provides an extraordinarily efficient permeability barrier to noxious compounds, rendering mycobacteria intrinsically resistant to many drugs (Brennan & Nikaido, 1995). Due to the paramount medical importance of M. tuberculosis, the ultrastructure of mycobacterial cell envelopes has been intensively studied for decades by electron microscopy. A thick, electron-transparent zone has been observed in the cell wall in stained thin sections of many mycobacterial species (Mineda et al., 1998; Paul & Beveridge, 1992) and was shown to comprise lipids (Paul & Beveridge, 1994). To account for the remarkable efficiency of the mycobacterial cell wall as a permeability barrier, Minnikin (1982) originally proposed a model (Fig. 1) in which the mycolic acids are covalently bound to the arabinogalactan–peptidoglycan co-polymer and form the inner leaflet of an asymmetrical bilayer. Other lipids extractable by organic solvents were thought to form the outer leaflet of this outer bilayer. X-ray diffraction studies of mycobacterial cell walls showed that the mycolic acids are oriented parallel to each other and perpendicular to the plane of the cell envelope (Nikaido et al., 1993). This provided experimental support for some fundamental aspects of the Minnikin model. Mutants and treatments affecting mycolic acid biosynthesis and the production of extractable lipids showed an increase of cell wall permeability and a drastic decrease of virulence, underlining the importance of the integrity of the cell wall for intracellular survival of M. tuberculosis (Barry et al., 1998). These indirect structural, biochemical and genetic
data are consistent with the existence of an outer lipid bilayer as proposed by Minnikin (1982). However, this model (Fig. 1) faced criticism mainly because electron microscopy of mycobacteria, in particular thin sections thereof, never showed evidence for an additional, outer lipid bilayer (Daffe & Draper, 1998; Draper, 1998). In addition, the exact localization of the extractable lipids and of the mycolic acids is unknown. One of the difficulties in providing additional experimental evidence for this model is the fact that lipid membranes are notoriously poorly preserved during chemical fixation and plastic embedding (Beveridge, 1999). Thus, direct evidence for an outer lipid bilayer in mycobacteria is lacking. Consequently, a periplasmic space as defined above has been regarded as hypothetical for mycobacteria (Daffe & Draper, 1998; Etienne et al., 2005). Recently, cryo-electron tomography of intact M. smegmatis and Mycobacterium bovis BCG cells revealed two lipid membranes. This is the first visualization of native outer membranes in mycobacteria (Hoffmann et al., 2008). Biologically important consequences are that mycobacteria possess a periplasmic space defined by two membranes, analogous to the situation in Gram-negative bacteria and have periplasmic and outer-membrane proteins that functionalize these cellular compartments.

**Principal nutrient pathways across the mycobacterial cell envelope**

The unique mycolic acid layer is an extremely efficient permeability barrier protecting the cell from toxic compounds and is generally thought to be the major determinant of the intrinsic resistance of mycobacteria to most common antibiotics, chemotherapeutic agents and chemical disinfectants (Brennan & Nikaido, 1995). The mycolic acid layer is functionally and structurally analogous to the outer membrane of Gram-negative bacteria, a similarity that merits a more detailed comparison. Three general and several specific pathways for transport across the outer membrane of Gram-negative bacteria exist. (i) Hydrophobic compounds penetrate the membrane via the lipid pathway by temporarily dissolving in the lipid bilayer. (ii) Small and hydrophilic compounds diffuse through water-filled protein channels called porins (Nikaido, 1994). Some of these diffusion channels show specificity towards certain classes of compounds such as maltodextrin (Dumas et al., 2000) or nucleosides (Maier et al., 1988). (iii) Polycationic compounds are thought to disorganize the outer membrane, thereby mediating their own uptake in a process termed ‘self-promoted uptake’ (Hancock et al., 1991). (iv) Certain compounds are specifically taken up by transporter proteins such as FhuA and FepA, which transport iron-loaded siderophores in an energy-dependent process across the outer membrane of Escherichia coli (Braun & Killmann, 1999). The nutrient molecules that have crossed the outer membrane need to pass through the periplasm. The mechanisms of these transport processes in M. tuberculosis are not known. After passage through the periplasm nutrients are taken up across the inner membrane by specific transporter proteins, often against a concentration gradient, using cellular energy. These inner-membrane transporters of M. tuberculosis have been the focus of a recent review (Content et al., 2005).

**Transport across mycobacterial outer membranes**

**Porin-mediated diffusion of hydrophilic solutes**

Porins are defined as non-specific protein channels in bacterial outer membranes that enable the influx of hydrophilic solutes (Nikaido, 2003). Channel-forming proteins that are functionally similar to porins of Gram-negative bacteria have been observed in many mycobacteria (Niederweis, 2003) and other closely related genera such as corynebacteria. MspA was discovered as the first porin of M. smegmatis (Niederweis et al., 1999). Deletion of mspA reduced the outer-membrane permeability of M. smegmatis to cephaloridine and glucose nine- and fourfold, respectively (Stahl et al., 2001). These results show that MspA is the major general diffusion pathway for hydrophilic solutes in M. smegmatis. Consecutive deletions of the two porin genes mspA and mspC reduced the number of pores 15-fold compared to wild-type M. smegmatis. The loss of porins lowered the permeability for glucose 75-fold and, concomitantly, the growth rate of M. smegmatis on plates and in liquid medium dropped drastically (Stephan et al., 2005). This showed for the first time that the porin-mediated influx of hydrophilic nutrients limited the growth rate of porin mutants. However, it is unknown which and how many nutrients are in low supply in the M. smegmatis porin mutants. Since MspA could not be expressed in M. smegmatis above wild-type levels (Stephan et al., 2005), it is also not clear whether the influx of nutrients really limits the growth rate of wild-type mycobacteria as suggested earlier (Jarlier & Nikaido, 1990). The fact that the lack of the MspA and MspC porins also caused a reduced uptake of phosphates and slower growth on low-phosphate plates (Wolschendorf et al., 2007) indeed suggested that the slow uptake of essential hydrophilic nutrients other than the carbon source may also contribute to the slow growth of M. smegmatis porin mutants.

The crystal structure of MspA represents the first such structure of any mycobacterial outer-membrane protein (Faller et al., 2004). The mere existence of these hydrophobic integral pore proteins provides strong, albeit indirect, support for the existence of an outer membrane in mycobacteria because proteins with open channels in the cytoplasmic membrane would be detrimental for any cell for at least two reasons: first, open pores in the inner membrane would lead to an immediate breakdown of the proton gradient and deprive the cell of energy; and second, small hydrophilic solutes such as many metabolic intermediates or nutrients would leak out of the cell. The crystal structure of MspA revealed an octameric goblet-like conformation with a single central channel 10 nm in length (Faller et al., 2004). This structure is different from...
that of the trimeric porins of Gram-negative bacteria, which have one pore per monomer and are approximately 5 nm long (Koebnik et al., 2000). Its structural features define MspA as the founding member of a new class of outer-membrane proteins. The crystal structure also revealed that the constriction zone of MspA consists of 16 aspartates (D90/D91). Thus, the zone of MspA with the smallest diameter is highly negatively charged (Faller et al., 2004). This most likely explains the previously observed preference of MspA for cations (Niederweis et al., 1999). The MspA pore provides an example of how outer-membrane transport proteins can contribute to the selectivity of mycobacteria to particular nutrients.

The existence of channel-forming proteins in M. tuberculosis and in M. bovis BCG has been demonstrated (Kartmann et al., 1999; Lichtinger et al., 1999; Senaratne et al., 1998). Uptake of serine but not of glycine was reduced in an ompATb mutant compared to wild-type M. tuberculosis. This was interpreted as proof that OmpATb is a porin, consistent with its apparent channel-forming activity in vitro (Raynaud et al., 2002b). However, the overall permeability of the outer membrane of M. tuberculosis was reduced at pH 5.5 compared to pH 7.2, although the levels of OmpATb in the outer membrane were strongly increased (Raynaud et al., 2002b).

Considering these contradictory results, it is doubtful that OmpATb has significant porin function in M. tuberculosis (Niederweis, 2003). The recent observation that a central domain of approximately 150 amino acids is sufficient for the channel activity of OmpATb in vitro does not contribute to the understanding of its biological functions (Molle et al., 2006). Pore-forming proteins of M. tuberculosis other than OmpATb are not yet known.

**Direct diffusion of hydrophobic solutes through the cell membranes**

Hydrophobic molecules, in particular nonelectrolytes, can easily diffuse through phospholipid bilayers. However, the lipopolysaccharide-containing outer membrane of Gram-negative bacteria constitutes a considerable permeability barrier that does not allow the penetration of even extremely hydrophobic β-lactam antibiotics (Nikaido et al., 1983). The lipids in mycobacterial cell walls are likely to be organized in a very unusual, asymmetrical bilayer (Nikaido et al., 1993). Differential scanning calorimetry showed that the lipids in mycobacterial cell walls have very high phase transition temperatures in the range of 60–70 °C. This is suggestive of a lipid domain of extremely low fluidity (Liu et al., 1995). Isolated cell walls of corynebacteria, which contain much shorter corymycolic acids, displayed a much lower temperature transition, suggesting that the fluidity of this lipid bilayer is mainly determined by the mycolic acids. Since direct diffusion of a hydrophobic molecule through a lipid membrane requires that it is dissolved in the lipid phase, the permeability of a particular membrane is directly correlated with its fluidity. This has been demonstrated directly by Nikaido and coworkers (Liu et al., 1996). It is concluded that the mycobacterial outer membrane presents a strong permeability barrier for hydrophobic molecules. On the other hand, there is emerging evidence that fatty acids rather than carbohydrates might be the dominant carbon source of M. tuberculosis after the onset of the immune response. This includes the requirement for isocitrate lyase for growth and persistence of M. tuberculosis in macrophages and in mice (McKinney et al., 2000), and the induction of expression of genes encoding enzymes involved in the β-oxidation of fatty acids in macrophages (Schnappinger et al., 2003) and mice (Dubnau et al., 2005; Timm et al., 2003). However, the sources and the types of fatty acids that may be utilized by M. tuberculosis, as well as the uptake pathways, are unknown.

**Transport across the mycobacterial inner membrane**

**Transporters of carbohydrates**

It has been widely documented that the soil bacterium M. smegmatis can grow on many carbon sources such as polyols, pentoses and hexoses (Edson, 1951; Franke & Schilling, 1944; Izumori et al., 1976). A recent comprehensive analysis of carbohydrate uptake systems revealed that M. smegmatis has 28 putative carbohydrate transporters (Tiggesmeyer et al., 2007). The majority of sugar transport systems (19/28) in M. smegmatis belong to the ATP-binding cassette (ABC) transporter family (Fig. 2a). M. smegmatis further possesses one putative glycerol facilitator of the major intrinsic protein (MIP) family, four sugar permeases of the major facilitator superfamily (MFS), of which one was assigned as a glucose transporter, and one galactose permease of the sodium solute superfamily (SSS). Thus, inner-membrane transport systems for polyols, pentoses and hexoses are predicted to exist in M. smegmatis (Fig. 2a; see also Supplementary Figs S1 and S2, available with the online version of this review).

*Only the numbers of the locus tags msme0000 to msme155 of the M. smegmatis mc²155 genome are shown. Locus tags are taken from the revised genome annotation by TIGR (http://www.tigr.org).

†This column contains information on representative homologues for which experimental information is available.

‡The following genome servers were used for BLASTP analysis: B, B. subtilis (http://genolist.pasteur.fr/SubtilList); C, E. coli (http://genolist.pasteur.fr/Colibri); S, S. coelicolor (www.avermitilis.ls.kitasato-u.ac.jp/blast_local/index.html); T, M. tuberculosis (http://genolist.pasteur.fr/TubercuList).

M. smegmatis did not grow on lactose, maltose and sucrose as sole carbon source (Titgemeyer et al., 2007). Franke & Schillinger (1944) obtained the same result for lactose and maltose, but observed respiration of M. smegmatis in the presence of sucrose. M. smegmatis has at least three inner-membrane transport systems with significant similarities to other bacterial disaccharide transporters (Table 1, Fig. S1). However, the substrate specificities of the transporters encoded by msme00501–00508 and msme00509–00517 are not known. Growth of bacteria on disaccharides as sole carbon sources requires enzymes that cleave the disaccharide and release the monosaccharides for further metabolism. The absence of proteins similar to known bacterial β-D-galactosidases ( LacZ of E. coli, BgaB of Bacillus circulans, MbgA of Bacillus megaterium, LacA of Streptomyces coelicolor) provides a molecular explanation for the inability of M. smegmatis to utilize lactose as a sole carbon source. By contrast, M. smegmatis has six homologues (MSMEG3191, 3577, 4901, 4902, 4685, 6477) of MalI of Bacillus subtilis, which hydrolyses maltose, longer maltdextrins up to maltohexose, isomaltose and sucrose (Schönert et al., 1999), and of the cytoplasmic trehalase TreC of E. coli, which cleaves trehalose 6-phosphate (Rimmele & Boos, 1994). It is conceivable that these enzymes are used in trehalose metabolism, considering the unusual importance of trehalose in mycobacteria (Murphy et al., 2005; Woodruff et al., 2004) and the observation that trehalose was the only disaccharide that was used by M. smegmatis as a sole carbon source. However, it cannot be excluded that some of the enzymes with similarities to TreC and MalF have roles in pathways distinct from trehalose metabolism.

Bioinformatic analysis of the genome of M. tuberculosis H37Rv revealed four ABC-type transporters and one permease of the MFS class for carbohydrates (Titgemeyer et al., 2007) (Fig. 2b). These ABC transporters have been described earlier in a global analysis of the M. tuberculosis genome (Braibant et al., 2000; Content et al., 2005). It is obvious that M. tuberculosis is poorly equipped with carbohydrate transport systems in comparison to M. smegmatis. Two of the operons, the lpgY–sugABC and the uspABC operons, are highly conserved between the two species. The proteins of the ABCsug and of the ABCusp systems share between 62 % and 80 % similar amino acids, compared to only 25–30 % similar amino acids for the ABCusp and the Rv2038c/Rv2039c/Rv2040c/Rv2041c systems. The similarities of all four ABC systems to known transporters outside the genus Mycobacterium is so low (<25 %) that substrates of these transporters cannot be predicted (Titgemeyer et al., 2007).

The ABCsug sugar transport system was predicted to be essential for virulence of M. tuberculosis in mice based on transposon site hybridization (TraSH) experiments (Sassetti & Rubin, 2003). Previously, it was suggested that this permease may transport maltose or maltodextrins (Borich et al., 2000; Braibant et al., 2000). However, the similarities both of ABCsug and of the corresponding substrate-binding protein LpgY to the maltose transporters and periplasmic maltose-binding proteins MalE of E. coli and S. coelicolor are very low (<25 %). Thus, it is questionable whether maltose is the substrate of ABCsug. This conclusion is supported by the fact that neither M. smegmatis, which has a highly similar ABCsug system, nor M. tuberculosis (Edson, 1951) grows on maltose as a sole carbon source. It has to be noted that similar uncertainties exist about the substrate specificities of the four other carbohydrate uptake systems of M. tuberculosis, including the ABCusp transporter that was proposed to transport sn-glycerol 3-phosphate based on low protein similarities (Braibant et al., 2000; Content et al., 2005). The Sugl transporter of the MFS class shows distinct sequence similarity to the glucose permease GlcP (28 %) of S. coelicolor and to the galactose (GalP, 24 %) and arabinose (AraE, 24 %) transporters of E. coli. Thus, the Sugl system may transport a monosaccharide.

Glycerol is used as the standard carbon source to grow M. tuberculosis; however, no uptake system is known or...
apparent by sequence similarity (Titgemeyer et al., 2007). Since M. tuberculosis grows with a generation time of 24 h and it has been shown that glycerol can directly diffuse through lipid membranes both in vitro (Paula et al., 1996) and in vivo (Eze & McElhaney, 1981), it is conceivable that the rate of glycerol intake by passive diffusion may be sufficient for growth. Incoming glycerol would then be converted by glycerol kinase (GlpK) to glycerol 3-phosphate to enter the route of central carbon metabolism (Fig. 2b). M. tuberculosis has one putative glycerol kinase that shows a high similarity to the two glycerol kinases of M. smegmatis (MSMEG6759, 77%, and MSMEG6756, 57%) and to the two glycerol kinases from S. coelicolor SCO0509 (75%) and SCO1660 (39%).

Comparison of inner-membrane sugar transporters of M. smegmatis and M. tuberculosis. The analysis of the carbohydrate uptake proteins in the genomes of M. smegmatis and M. tuberculosis confirms the very early phenotypic observations that the saprophytic mycobacteria have a much broader spectrum of substrates that they can use as sole carbon and energy sources (Edson, 1951). It is striking that the genome of M. tuberculosis has only five permeases for carbohydrate uptake compared to the 28 of M. smegmatis. This suggests that the phagosome does not provide an environment rich in diverse sugars. The tantalizing conclusion is that an experimental analysis of the substrate specificity of the inner-membrane carbohydrate transporters of M. tuberculosis may reveal the carbon sources available in the phagosome of human macrophages and/or in other cellular hideouts of M. tuberculosis inside the human body.

Transports of lipids

Several lines of evidence strongly suggest that M. tuberculosis switches from a carbohydrate to a fat diet after the onset of the adaptive immune response. (i) Biochemical studies suggest that in chronically infected lung tissues, fatty acids may be a major source of carbon and energy for M. tuberculosis (Wheeler et al., 1990). (ii) During the first 10 days of infection of mice, M. tuberculosis requires the sugar transporter SugAB for survival (Sassetti & Rubin, 2003). Thereafter, enzymes such as isocitrate lyase and malate synthases are essential for virulence ( McKinney et al., 2000). This indicates that lipids are the major carbohydrate source of M. tuberculosis because the glyoxylate shunt is required for running the citric acid cycle on acetate, which is produced by degradation of lipids through β-oxidation. (iii) M. tuberculosis possesses four genes encoding putative phospholipases C, plcA, plcB, plcC and plcD. These genes are required for virulence of M. tuberculosis in mice (Raynaud et al., 2002a). The fact that the phospholipases C are attached to the cell wall by lipid anchors argues for a role of these enzymes in the controlled release of fatty acids, probably from phospholipids of the phagosomal membrane. However, while several proteins have been identified in M. tuberculosis as being involved in the transport of lipids from the cytoplasm to the periplasm (Jackson et al., 2007), the proteins involved in the transport of lipids across the outer membrane are as yet unknown. By contrast, the mechanisms that govern the uptake of exogenous fatty acids are well established in E. coli (Dirusso & Black, 2004). When the cell encounters long-chain fatty acids in the environment, these bind to outer-membrane protein FabL and via a ligand-induced conformational shift within the protein, are transported into the periplasmic space. The more acidified environment of the periplasmic space promotes the formation of uncharged fatty acid molecules, which partition into and flip across the inner membrane. Within the cytosol, the acyl-CoA synthase FabD partitions into the inner membrane, where it functions in the vectorial esterification of the long-chain fatty acids (Dirusso & Black, 2004). Consistent with the importance of lipid uptake, M. tuberculosis possesses numerous homologues of FabD proteins (Trivedi et al., 2004).

Transports of phosphorus-containing solutes

Phosphorus is indispensable for energy supply, the biosynthesis of nucleic acids and phospholipids, and many other cellular processes. While inorganic phosphate is the preferred source of phosphorus, many bacteria can also take up organic phosphates and release phosphate by the action of periplasmic phosphatases such as PhoA. Gram-negative bacteria employ sophisticated transport mechanisms to acquire phosphorus-containing nutrients from the environment. E. coli uses four phosphate transport systems, Pst, Pit, GlpT and UhpT, to translocate inorganic phosphate across the inner membrane (van Veen, 1997). Part of the Pst system is the periplasmic protein PstS, which binds to and transfers phosphate to the transmembrane components PstA and PstC. PstB hydrolyses ATP and delivers energy for phosphate translocation across the inner membrane by PstA/PstC. Pst systems bind and transport phosphate with binding constants and apparent transport K_m values in the submicromolar range. M. tuberculosis contains several copies of the genes encoding the Pst system (Brabant et al., 1996). Two Pst components, PstS1 and PstS2, have been shown to be virulence factors in M. tuberculosis (Peirs et al., 2005; Sassetti & Rubin, 2003). Further, M. tuberculosis contains two genes, pitA and pitB, which encode putative constitutive inorganic phosphate transporters (Content et al., 2005). The physiological role of the Pit transporters is unclear.

The single pstSCAB operon of the fast-growing M. smegmatis encodes a high-affinity Pst system with an apparent K_m value of 40 mM phosphate. A second high-affinity phosphate uptake system of M. smegmatis is encoded by the phnDCE operon (Gebhard et al., 2006). However, even a phnD pstS double mutant did not show a reduced phosphate uptake, suggesting the presence of a third high-affinity phosphate uptake system of M. smegmatis (Gebhard et al., 2006). Considering the presence
of three high-affinity phosphate uptake systems that are inducible at low phosphate concentration in *M. smegmatis*, it is unclear why the *pstB* mutant showed reduced phosphate transport (Bhatt *et al.*, 2000). Taken together, these results underline the importance of phosphate uptake for mycobacteria. The transcriptional profiles of *M. tuberculosis* and *Salmonella enterica* in infected macrophages revealed that the proteins involved in inorganic phosphate transport are upregulated (Eriksson *et al.*, 2003; Schnappinger *et al.*, 2003), indicating that phosphate levels inside phagosomes of macrophages are indeed limited. Consistent with this conclusion, genes encoding efficient phosphate transport systems were found to be essential for the survival of *M. tuberculosis* in macrophages and mice (Rengarajan *et al.*, 2005; Sassetti & Rubin, 2003). However, it is unknown how inorganic or organic phosphates cross the outer membrane of *M. tuberculosis*. Since direct diffusion of phosphates through model lipid membranes is extremely slow [permeability coefficient of the monon-5 \times 10^{-12} \text{cm s}^{-1} (Chakrabarti & Deamer, 1992)] it appears likely that slowly growing mycobacteria also use outer-membrane pore proteins for uptake of phosphate. Indeed, the existence of a porin with anion specificity has been demonstrated (Lichtinger *et al.*, 1999). This porin still awaits discovery.

### Transporters of sulfur-containing solutes

Sulfur is essential in cells for biological activities such as translation initiation and maintenance of the redox potential. Transposon insertions in the cysA and subl genes of *M. bovis* BCG yielded methionine auxotrophs. These mutants were resistant to chromat and did not take up sulfate. These results identified the products of the genes *cysTWA* and *subl* as components of a sulfate permease and indicated that this transporter is the sole sulfate transporter of *M. bovis* BCG (McAdam *et al.*, 1995; Woff *et al.*, 2002). The sensitivity of sulfate uptake to azide and 1,3-dicyclohexylcarbodiimide are characteristic of ABC transporters. Survival of the cysA and subl mutants in mice was not different from wild-type *M. bovis* BCG. This indicated that, in the host, methionine may be a more important sulfur source than sulfate for growth of the *M. tuberculosis* complex. This may also explain how *Mycobacterium leprae* remains a pathogen, despite being a natural methionine auxotroph because of its loss of *cysTWA* for sulfate transport (Wood, 1995). An alternative explanation may be that other putative sulfate transporters such as the predicted sulfate permease (SulP) of *M. tuberculosis* are induced *in vivo* and compensate for the loss of the CysTWA transporter (Content *et al.*, 2005).

### Transporters of nitrogen-containing solutes

Nitrogen is an essential component of nearly all complex macromolecules in a bacterial cell, such as proteins, nucleic acids and cell wall components. Ammonium is the preferred nitrogen source of many bacteria. In enteric bacteria, diffusion of uncharged ammonia (NH₃) through the cytoplasmic membrane into the cell is sufficient to support growth in the presence of high amounts of ammonium (NH₄⁺) in the growth medium. Only when diffusion across the cell envelope becomes limiting for growth is the ammonium transporter AmtB synthesized. Homologues of AmtB exist in *M. tuberculosis* and *M. smegmatis* (Nolden *et al.*, 2001). However, no biochemical data are available for ammonium uptake by mycobacteria and the role of AmtB in this process.

Nitric oxide (NO) is generated in large amounts within macrophages and restricts the growth of *M. tuberculosis*. Nitrate can be produced by oxidation of nitric oxide and is an alternative source of nitrogen for bacteria within the human host. Early work in *E. coli* had suggested that *narK* was involved only in nitrite export (Rowe *et al.*, 1994), and so the homologous *narK2* in *M. tuberculosis* was annotated as a 'nitrite extrusion protein'. More recent work with an *E. coli* *narK* *narU* double mutant indicated that the two proteins could transport nitrate into and nitrite out of the cell (Clegg *et al.*, 2002; Jia & Cole, 2005). In *M. tuberculosis*, four genes, *narK1* through *narK3* and *narU*, are homologous to *E. coli* *narK* and *narU*. Since *M. tuberculosis* is unable to reduce nitrite, which could accumulate to toxic levels, it must then be exported out of the cell. The *M. tuberculosis* *narK2* was shown to complement this *E. coli* double mutant, supporting a role for *narK2* in nitrate reduction by coding for a transporter of nitrate into and nitrite out of the cell (Sohaskey & Wayne, 2003). Nitrate reduction by *M. tuberculosis* is regulated by control of nitrate transport into the cell by NarK2. It is proposed that NarK2 senses the redox state of the cell, possibly by monitoring the flow of electrons to cytochrome oxidase, and adjusts its activity so that nitrate is transported under reducing, but not oxidizing, conditions (Sohaskey, 2005). Inhibition of nitrate transport by oxygen has been documented in other bacteria (Moir & Wood, 2001). It is intriguing that *M. tuberculosis*, classified as an obligate aerobe, should have such intricate control of an anaerobic enzyme system. Transcription of *narK2* is controlled by DosR/DevR, which responds to hypoxia and NO (Ohno *et al.*, 2003; Voskuil *et al.*, 2003). Both the transcription of the *narK2* gene and the activity of NarK2 are controlled by similar signals (Sohaskey, 2005).

### Transporters of inorganic cations

Metal ions such as Fe²⁺/Fe³⁺, Cu⁺/Cu²⁺ and Zn²⁺ play structural and catalytic roles in metalloenzymes. Genome analysis of *M. tuberculosis* revealed 28 genes encoding a broad repertoire of putative metal ion transporters. They comprise eight families of secondary active transporters and three families of primary active transporters, including twelve ‘P’-type ATPases, and represent approximately a quarter of all transporters in this organism. Potential metal ion specificities include K⁺, Na⁺, Cu²⁺, Cd²⁺, Zn²⁺, Mn²⁺, Mg²⁺, Ca²⁺, Co²⁺, Ni²⁺, Fe²⁺/³⁺, Hg²⁺, AsO₃⁻ and AsO₄³⁻. Seventeen of these transporters are also...
encoded as complete open reading frames in *M. leprae*, suggesting a role in intracellular survival. The properties of these transporters, including the NRAMP orthologue MntH, which transports manganese ions in other bacteria, have been reviewed recently (Agranoff & Krishna, 2004; Content et al., 2005). Here we summarize only the new findings for the uptake of iron by *M. tuberculosis*.

Throughout the living world, iron is contained in the active centres of most redox enzymes. Because iron occurs in the insoluble Fe$^{3+}$ form under oxic conditions ($10^{-9}$ M Fe$^{3+}$ in soil and water) (Ratledge & Dover, 2000), proteins and siderophores with high binding affinity are required to make Fe$^{3+}$ biologically available. *M. tuberculosis* produces salicylate-containing siderophores named mycobactins. The more polar form (carboxymycobactin) is released into the medium, whereas the less polar form (mycobactin) remains cell-associated (Ratledge & Dover, 2000). Upon binding by siderophores, Fe$^{3+}$ is transported into the bacterium and released from the siderophore, possibly by reduction. In most bacteria, Fe$^{3+}$–siderophore complexes bind to specific receptor proteins on the cell surface and are actively transported into the cytoplasm by specialized proteins that belong to the family of ABC transporters (Braun & Killmann, 1999). The ABC transporter IrtAB is required by *M. tuberculosis* to replicate in iron-deficient medium and to use Fe$^{3+}$–carboxymycobactin as an iron source, indicating that IrtAB is involved in the transport of Fe$^{3+}$–carboxymycobactin (Rodriguez & Smith, 2006). Deletion of the *irtAB* genes also reduced the ability of *M. tuberculosis* to survive in macrophages and in the lungs of mice. However, the lack of *irtAB* does not completely eliminate replication of *M. tuberculosis* in iron-deficient conditions, which indicates that other transporters can partially compensate for the lack of IrtAB (Rodriguez & Smith, 2006). Given the importance of iron, this is not surprising because pathogenic bacteria often have multiple pathways for iron acquisition. The genome of *M. tuberculosis* does not reveal other obvious siderophore transporters (Rodriguez, 2006). However, there are numerous ABC transporters for which the substrates are unknown; one or more of these could contribute to iron uptake.

**Transporters of amino acids**

Many micro-organisms use amino acids as a source of energy and/or nitrogen, and also for biosynthetic purposes. It was shown early in seminal papers by Yabu that D-amino acids are taken up rapidly by mycobacteria while the L-forms are transported at a much lower rate (Yabu, 1967, 1970, 1971). These results can be attributed to the specificity of the inner-membrane transporters for the natural form of amino acids. It was also found early on that *M. tuberculosis* cannot utilize amino acids to support metabolism, in contrast to saprophytic mycobacteria (Edson, 1951). Nevertheless, some amino acids are taken up by *M. tuberculosis* and *M. bovis* BCG (Seth & Connell, 2000). In particular, uptake of arginine was examined because arginine also plays an important role in the cellular immune response as the substrate of the inducible nitric oxide synthase (iNOS), which generates nitric oxide to kill bacterial and parasitic pathogens in macrophages (Chan et al., 2001; Nathan & Shiloh, 2000). Thus, competition between the pathogen and macrophages for arginine has been suggested to contribute to the outcome of infection (Mills, 2001). Not surprisingly, *M. tuberculosis* has several genes encoding putative L-arginine uptake transporters: Rv0522, Rv1979c, Rv1999c, Rv2320c and Rv3253c (Cole et al., 1998). Transport of L-arginine, but not of L-lysine and L-ornithine, was reduced by 70% in a mutant of *M. bovis* BCG lacking the gene homologous to *rv0522*. This identified Rv0522 (GabP) as an arginine transporter of *M. tuberculosis* (Seth & Connell, 2000). The remaining 30% of L-arginine transport activity and the uptake of other cationic amino acids by the mutant are probably mediated by other amino acid permeases.

**Conclusions**

It is apparent that the uptake of nutrients by mycobacteria is not well understood, despite its importance for understanding the physiology and pathogenicity of *M. tuberculosis* and the availability of a wealth of genomic information. The knowledge gap begins with the uncertainty about which are the main essential nutrients of *M. tuberculosis* inside the host. This obviously depends on the location of *M. tuberculosis* inside the human body, which may vary from phagosomes in macrophages and dendritic cells (Russell, 2003) to granulomas (Ulrichs & Kaufmann, 2006) and even fat cells (Neyrolles et al., 2006). There is clearly a need to determine the nutrients available in those different environments and to identify the proteins that are employed by *M. tuberculosis* to take up these nutrients. A solid functional, biochemical and structural analysis of these membrane proteins is a prerequisite to understanding the transport processes across both the inner and outer membrane of *M. tuberculosis*. Comparisons with the saprophyte *M. smegmatis* are not expected to contribute much to understanding the physiology and virulence of *M. tuberculosis*. However, studying nutrient uptake pathways in *M. smegmatis* should reveal the principal mechanisms by which the permeability barriers in mycobacteria can be overcome. Examples are presented in this review. It is striking that *M. tuberculosis* uses far fewer carbohydrate transporters than *M. smegmatis*. Further, the set of outer-membrane porins is apparently also different. These differences probably represent adaptations of *M. tuberculosis* to its slower growth (Cox & Cook, 2007) and to its very different natural habitat.

The comprehensive identification and the biochemical and structural characterization of the nutrient transporters of *M. tuberculosis* will not only promote our understanding of the physiology of this important human pathogen, but might also be exploited to improve tuberculosis chemotherapy. In particular, outer-membrane proteins
offer the tremendous advantage as drug targets that inhibitors may not need to cross the outer membrane, which is an extremely efficient permeability barrier in mycobacteria. In addition, they are likely to represent novel drug targets because they do not appear to show any similarity to other proteins (Faller et al., 2004). It is my hope that this review will stimulate experimental work to examine nutrient transport pathways in mycobacteria.

Acknowledgements

I thank all present and past members of the Mycolab for excellent contributions and stimulating discussions. In particular, I thank Jason Huff for thoughtfully editing the manuscript. The anonymous reviewers deserve credit for valuable suggestions about how to improve the manuscript. Sequence data for Mycobacterium smegmatis were obtained from The Institute for Genomic Research website (http://www.tigr.org). This work was supported by grant AI063432 of the National Institutes of Health.
