The outer membrane protein OprQ and adherence of *Pseudomonas aeruginosa* to human fibronectin

Abraham Arhin and Cliff Boucher

The University of Texas at Tyler, 3900 University Blvd, Tyler, TX 75701, USA

Outer membrane proteins of the Gram-negative organism *Pseudomonas aeruginosa* play a significant role in membrane permeability, antibiotic resistance, nutrient uptake, and virulence in the infection site. In this study, we show that the *P. aeruginosa* outer membrane protein OprQ, a member of the OprD superfamily, is involved in the binding of human fibronectin (Fn). Some members of the OprD subfamily have been reported to be important in the uptake of nutrients from the environment. Comparison of wild-type and mutant strains of *P. aeruginosa* revealed that inactivation of the oprQ gene does not reduce the growth rate. Although it does not appear to be involved in nutrient uptake, an increased doubling time was reproducibly observed with the loss of OprQ in *P. aeruginosa*. Utilizing an oprQ–xylE transcriptional fusion, we determined that the PA2760 gene, encoding OprQ, was upregulated under conditions of decreased iron and magnesium. This upregulation appears to occur in early exponential phase. Insertional inactivation of PA2760 in the *P. aeruginosa* wild-type background did not produce a significant increase in resistance to any antibiotic tested, a phenotype that is typical of OprD family members. Interestingly, the in trans expression of OprQ in the ΔoprQ PAO1 mutant resulted in increased sensitivity to certain antibiotics. These findings suggest that OprQ is under dual regulation with other *P. aeruginosa* genes. Intact *P. aeruginosa* cells are capable of binding human Fn. We found that loss of OprQ resulted in a reduction of binding to plasmatic Fn in vitro. Finally, we present a discussion of the possible role of the *P. aeruginosa* outer membrane protein OprQ in adhesion to epithelial cells, thereby increasing colonization and subsequently enhancing lung destruction by *P. aeruginosa*.

INTRODUCTION

*Pseudomonas aeruginosa* is an opportunistic Gram-negative pathogen that causes infections in individuals with altered immune systems, such as burn, HIV, nosocomial and neutropenic patients (DiGiandomenico et al., 2007; Sadikot et al., 2005). This pathogen is also notorious for its role in infections of the respiratory tract of patients with cystic fibrosis (Wagner & Iglewski, 2008). The ability of *P. aeruginosa* to cause such a wide range of infections is, in part, due to the outer membrane proteins that it expresses (Wu et al., 2005). One major class of outer membrane proteins (Opps), containing members that function as virulence factors, is the OprD superfamily (Tamber et al., 2006).

Outer membrane proteins are involved in many aspects of growth and development of the bacterial cell (Hancock & Brinkman, 2002). The outer membrane protein OprD superfamily consists of 19 members, all of which display at least 46% similarity at the amino acid level (Tamber et al., 2006). The members of this family participate in amino acid and peptide transport, antibiotic uptake, and transport of carbon sources (Hancock & Brinkman, 2002). In addition, the permeability of the *P. aeruginosa* outer membrane has been attributed, at least in part, to the surface expression of the OprD class of proteins (Strateva & Yordanov, 2009). Although OprD homologues may perform multiple roles, it does not appear that the function of the channels of this family is non-specific. Each member of the OprD subfamily, at least those involved in nutrient uptake, seems to have a very narrow specificity (Tamber & Hancock, 2003). For example, *P. aeruginosa* OprD, a homologue of the *Escherichia coli* porin OmpF, exists in the outer membrane in a β-barrel configuration, and is known to play a significant role in the uptake of basic amino acids and resistance to imipenem and carbapenem (Hancock & Brinkman, 2002; Lister, 2002). The exact role for some members, such as OprQ and OprI, has yet to be determined. Recently, the group of Tamber has reported that a specific nutrient substrate for OprQ and OprI cannot be identified, at least in the *P. aeruginosa* PAK background (Hancock & Brinkman, 2002).

It has been reported that as many as 100 outer membrane proteins are produced by *P. aeruginosa* (Hancock & Brinkman, 2002). Proteins localized to the outer membrane...
of *P. aeruginosa* have been shown not only to be involved in nutrient uptake and antibiotic resistance, but also to participate in this bacterium’s pathogenicity. Some *P. aeruginosa* outer membrane virulence factors, such as XcpQ (Brok et al., 1999; Robert et al., 2005), XqhA (Martinez et al., 1998; Michel et al., 2007), EstA (Wilhelm et al., 1999), OprG (McPhee et al., 2009) and OprE (Yamano et al., 1998), have become areas of active research. However, there remain many Ops that have not been investigated and their respective roles in *P. aeruginosa* have not yet been identified. One such potential virulence factor is the *P. aeruginosa* outer membrane protein OprQ. It has been reported that OprQ is a member of the OprD superfamily of proteins (Jaouen et al., 2001, 2006; Tamber et al., 2006). Studies of OprQ function in *Pseudomonas fluorescens* suggest that it plays a role significantly different from that of other members of the OprD subfamily. In this regard, OprQ in *P. fluorescens* has been shown to bind fibronectin (Fn) *in vitro* (Rebiere-Huët et al., 2002). The function of *P. aeruginosa* OprQ in growth, antibiotic resistance and the colonization of the host is currently not known, but these studies suggest that OprQ is directly involved in the disease process.

In this study, we report the unexpected finding that loss of OprQ resulted in an increased rate of growth. We also found that in the inactivated oprQ background, the overexpression of OprQ may increase *P. aeruginosa* sensitivity to antibiotics. In addition, we determined that OprQ is upregulated under conditions of low iron and magnesium. Since these conditions are thought to mimic conditions at known sites of *P. aeruginosa* infection, it is possible that OprQ is needed for the establishment of disease. Finally, we report that OprQ in *P. aeruginosa* is potentially involved in adhering to Fn, thus resulting in the initial colonization of the host epithelial tissue.

**METHODS**

**Bacterial plasmids, strains and culture conditions.** The strains, primers and plasmids used in this study are listed in Table 1. PAA2760 is a derivative of the *P. aeruginosa* strain PAO1. All strains were grown in the minimal medium M63, *Pseudomonas Isolation Agar* (PIA; Difco) or *Luria–Bertani* (LB; Difco) medium, with supplementation as indicated.

Using the PAO1 genomic database, oligonucleotides were designed to encompass the sequence between PA2760 and the upstream gene PA2759. Primers 2760F-3 and 2760R-1 for the DNA sequence of PA2760 were used in a PCR to amplify the gene for cloning. The PCR product was then cloned into the vector pCR2.1 to create the plasmid pAA2760Pr using the TOPO TA cloning kit (Invitrogen). This plasmid was then digested with the restriction enzyme EcoRI (Invitrogen), and the 232 bp promoter fragment was isolated and subsequently cloned into the EcoRI-digested vector pVDX18 (Konyecsni & Deretic, 1988), creating the fusion plasmid pAA2760-XylE.

To generate the suicide vector pAA2760Tc, the primers 2760F-1 and 2760R-2 were used in a PCR to amplify a 1.5 kb fragment of the

</table>
The newly created plasmid pCR2.1 (Invitrogen), creating plasmid pAA2760. This plasmid was double-digested with the restriction enzymes HindIII and XbaI (both from New England Biolabs), and the fragment containing the PA2760 gene was extracted from an agarose gel via a PureLink Quick Gel Extraction kit (Invitrogen). The plasmid vector pUC19 (New England Biolabs) was also double-digested with HindIII/XbaI and subsequently ligated with the PA2760 HindIII/XbaI fragment. E. coli strain DH5α, harbouring the newly constructed pUC2760 plasmid, was grown on agar (Difco plates containing 50 µg ampicillin ml⁻¹ (Invitrogen). The isolated pUC2760 plasmid DNA was further digested with the restriction enzyme BstEII (Invitrogen), purified and blunt-ended with large fragment Klenow (Invitrogen). The plasmid pUCt, containing a cassette that confers tetracycline resistance (TcR), was digested with PstI. The 1.5 kb tetracycline resistance gene cassette was isolated from a 1 % agarose gel and blunt-ended. The vector (pUC2760) and insert (TcR cassette) were ligated in the presence of 5 % PEG 1000 in order to concentrate the blunt-ended DNA fragments. Following ligation, DH5α cells were transformed with the ligated DNA and plated onto LB agar plates containing 10 µg tetracycline ml⁻¹ (Invitrogen), and the suicide vector pAA2760Tc containing the tetracycline insertion was identified via digestion with HindIII and XbaI and visualization on a 1 % agarose gel.

For complementation of the OprQ mutant, we created the plasmid pAA2760WT. Using the primers 2760F-1 and 2760R-3 in a PCR, we amplified the complete coding region of the oprQ gene. The amplified gene was cloned into the pCR2.1 vector (Invitrogen). The wild-type sequence of the PCR fragment was verified by sequencing using the Beckman CEQ 8000 Genetic Analysis System (Beckman Coulter). The newly created plasmid pAAOprQ was digested with EcoRI, and the 1.9 kb oprQ gene fragment was gel-purified and cloned into the EcoRI-digested plasmid pVDtac-39 (Deretic et al., 1987). All bacterial triparental conjugations were carried out using the donor E. coli DH5α strain carrying the plasmids pAA2760-Xyle and pAA2760WT with conjugates grown in LB supplemented with either ampicillin (50 µg ml⁻¹) or tetracycline (10 µg ml⁻¹), respectively. Recipient PAO1 was grown in LB and E. coli harbouring the helper plasmid pRK2013 (Figurski & Helinski, 1979) in LB with kanamycin (50 µg ml⁻¹). Each strain was grown overnight in 5 ml of medium, spun, washed in sterile saline and resuspended in 0.3 ml LB medium. The Pseudomonas recipient strain, donor DH5α, and the helper E. coli were combined (0.9 ml total) and passed through a 0.45 µm pore-size filter. The filter was placed on an LB plate and grown overnight at 37 °C. The bacterial growth from the filter was plated on PIA plates with either 1000 µg carbenicillin ml⁻¹ or 150 µg tetracycline ml⁻¹. Growth of P. aeruginosa strains for doubling time determination was performed using both LB and M63 media supplemented with 1 % glucose or glycerol (as carbon source), and either 0.2 % potassium nitrate or ammonium sulfate (as nitrogen source). c.f.u. were determined by serial dilution in 0.8 % sodium chloride and plating on LB media. Growth of P. aeruginosa strains analysed for xyle promoter activity was performed using M63 medium or M63 medium containing either FeCl₃ or MgSO₄ supplement, as indicated. All P. aeruginosa strains were grown to an OD₆₀₀ of 1.5 and 1 for iron and magnesium conditions, respectively. Upon reaching the appropriate OD₆₀₀, the P. aeruginosa cells were spun, washed and assayed as described below.

Electroporation and generation of the insertional mutant PAA2760. The newly created pAA2760Tc plasmid was used via electroporation to transform the wild-type P. aeruginosa strain PAO1 using the method of Smith & Igleski (1989). Briefly, to create electroporant P. aeruginosa cells, 500 µl of 300 mM sucrose was added to a microcentrifuge tube and approximately 3 mg of PAO1 cells, grown overnight in LB at 37 °C, was suspended in the sucrose solution. The P. aeruginosa cells were washed twice, and the final pellet was resuspended in 40 µl 300 mM sucrose. The electroporation-resistant P. aeruginosa was kept on ice for the remainder of the procedure. Five microlitres of pAA2760Tc DNA was added to the PAO1 cell pulsed at 3.0 kV mm⁻¹ using a Bio-Rad Electropulsor, 1 ml of LB broth was added, and the cells were incubated at 37 °C with shaking for 1 h. Cells were then plated (100 µl) onto LB agar plates containing 50 µg tetracycline ml⁻¹ and incubated overnight at 37 °C. Possible PA2760 knockout mutants were screened by replica plating on LB agar plates containing 500 µg carbenicillin ml⁻¹. Since the pUC19 plasmid is non-replicative in PAO1, sensitivity to carbenicillin (Carbβ) and resistance to tetracycline (TetR) were used to ensure that the oprQ gene was knocked out during electroporation. Carbenicillin sensitivity indicates the loss of the pUC19 plasmid. The PAO1 2760::TetR conjugant was verified for proper insertion of the genetic cassette by PCR using the primers 2760F-2 and 2760R-2, which flank the tetracycline insertion site.

Xyle assays. The catechol-2,3-dioxygenase (Xyle) activity of the OprQ transpositional fusion was assayed as described by Schweizer & Hoang (1995). Three separate protein extracts were prepared by growing conjugated cells overnight in M63 medium supplemented with 300 µg carbenicillin ml⁻¹. One millilitre of a P. aeruginosa overnight culture was used to inoculate a fresh solution of M63 in a 1:100 dilution, and the culture was grown at 37 °C with shaking until the appropriate OD₆₀₀ was reached (see above). The concentrations of magnesium and iron used for each experimental condition were as follows: (i) regular magnesium, 1.0 mM MgSO₄·7H₂O; (ii) low magnesium, 0.2 mM MgSO₄·7H₂O; (iii) regular iron, 0.1 M FeCl₃; and (iv) low iron, 0.01 M FeCl₃. All cultures were centrifuged at 10 000 r.p.m. for 10 min. The cells were then resuspended in 5 ml lysis buffer (50 mM potassium phosphate buffer, pH 7.5, 10 % acetone; Sigma-Aldrich). Cells were sonicated with a Branson cell sonifier for 1 min on ice with no interruptions. The disrupted cells were centrifuged cold and protein concentration was determined by the Bradford method in a Beckman Coulter spectrophotometer at 375 nm. Samples were prepared by adding to a 3 ml cuvette (Bio-Rad) the following: 2.5 ml H₂O, 0.3 ml 0.5 M potassium phosphate buffer and 0.1 ml 10 M catechol, all at room temperature. The correct amount of extract was added to equilibrate samples to 30 µg protein ml⁻¹, except the blank, which received no protein. Samples were added immediately and inverted two to three times to mix thoroughly. Readings were done at 375 nm, for 150 s with a 2.5 s interval. For each condition, regular and low iron or magnesium, a total of three independent sample protein extracts were analysed.

Antibiotic disk diffusion assay. Disks saturated separately with cefotaxime (30 µg), gentamicin (10 µg), amoxicillin/clavulanic acid (30 µg), erythromycin (15 µg), vancomycin (30 µg), levofloxacin (5 µg), ampicillin (10 µg), pipercillin (100 µg), chloramphenicol (2 µg), neomycin (30 µg), meropenem (10 µg) and aztreonam (30 µg) were applied to Mueller–Hinton agar plates containing P. aeruginosa strain PAO1, PAA2760 or PAA2760 carrying wild-type oprQ. The plates were incubated for 18 h at 37 °C. At the end of the incubation period, the diameters (mm) of the zones of growth inhibition were measured. Replicates for antibiotic susceptibility determination were performed for each strain using separate inoculations from individual cultures.

Determination of MIC. The MICs of colistin, ciprofloxin, imipenem monohydrate, tetracycline and tobramycin sulfate at starting concentrations of 16, 10, 5, 0.5, 0.05, 0.05, 0.005 and 10 µg ml⁻¹, respectively, were determined by twofold serial dilution using a sterile 96-well flat-bottomed microtitre plate, as described by Andrews (2001). The MICs of each individual strain were determined from at least three independent assays.
**Transcription and expression of OprQ is increased under stress conditions**

Under conditions of poor oxygenation, Jaouen et al. (2006) revealed, using RT-PCR, that the *P. fluorescens oprQ* gene is overexpressed. Oxygen stress and the induction of an OprD family outer membrane protein are not without precedents. It has been reported that OprE in *P. aeruginosa* is similarly induced in oxygen-depleted environments (Yamano et al., 1993). In order to identify other potential stressors that may induce the expression of the *oprQ* gene, the PA2760 promoter region, an intergenic sequence containing a potential promoter-binding site of the stress response sigma factor RpoH, was cloned into a *xylE* vector to analyse the expression of OprQ under varying conditions, such as that which might be encountered in the infection site. Comparisons were made between PA01, harbouring the PA2760-*XylE* plasmid, grown in M63 medium supplemented with regular magnesium (1.0 mM MgSO₄·7H₂O) and iron (0.1 mM FeCl₃) and M63 medium supplemented with low magnesium (0.2 mM MgSO₄·7H₂O) and iron (0.01 mM FeCl₃). Exposure to conditions of low magnesium resulted in a fivefold increase in transcription of the *oprQ* gene (Fig. 2). An even greater effect on promoter activity was observed when the strains were placed under low-iron stress. Under this condition, a 13-fold increase in *oprQ* promoter activity was observed (Fig. 2). These results suggest that OprQ is required for survival under conditions where *P. aeruginosa* is exposed to adverse growth conditions.

**OprQ and antibiotic resistance**

The ability of *P. aeruginosa* to be resistant to such a wide range of antibiotics is due to the outer membrane porins that it produces (Strateva & Yordanov, 2009). In particular, members of the OprD outer membrane protein superfamily have been shown to function in antibiotic resistance (Tamber et al., 2006). Since OprQ does not appear to play a significant role in growth, and given the potential role in antibiotic resistance, we hypothesized that OprQ affects the sensitivity of *P. aeruginosa* to these antimicrobials. It has been reported that OprQ is not important for carbapenem resistance (Okamoto et al., 1999). Therefore, we expanded this analysis of *P. aeruginosa* sensitivity upon inactivation of the *oprQ* gene to include 18 different antibiotics (gentamicin, neomycin, amoxicillin/clavulanic acid, ampicillin, piperacillin, levoflaxin, ciprofloxacin, meropenem, imipenem, cefalulodin, cefotaxime, colistin, vancomycin, tetracycline, substitution of glucose and potassium nitrate with glycerol and ammonium sulfate resulted in the same growth phenotype, suggesting that the increased doubling time is independent of the carbon or nitrogen source. These results indicate that OprQ is not required for the uptake of essential nutrients for growth. Furthermore, the observation of an increased growth rate suggests that OprQ is involved, directly or indirectly, in the regulation of other proteins/porins that are important in *P. aeruginosa* growth.

**RESULTS**

**Growth rate increase upon loss of OprQ**

The OprD family of porins is diverse, with a few members participating in nutrient acquisition from the environment (Hancock & Brinkman, 2002; Tamber & Hancock, 2003). As a member of this OprD subfamily, it is possible that the *P. aeruginosa* OprQ participates in nutrient uptake. One earlier study using a transposon *oprQ* mutant in the *P. aeruginosa* PAK background was unable to determine a specific amino acid transported by PA2760 (Tamber et al., 2006). It remains possible that OprQ is involved in the overall growth of *P. aeruginosa*. To further investigate the growth phenotype for OprQ in the *P. aeruginosa* PA01 wild-type background, we insertionally inactivated the oprQ gene using a tetracycline resistance gene cassette. The parent and mutant strains were grown on minimal M63 medium to determine whether any phenotypic changes could be observed. Interestingly, *P. aeruginosa* strain PA2760, in which OprQ expression was disrupted, had a significant increase in growth rate as compared with the PA01 parent when cultured in LB medium (Fig. 1). As seen in Fig. 1, the faster doubling time for PA2760, 29.9 min, was retarded back to the wild-type rate of 44 min when pAA2760WT was introduced into the OprQ mutant.
tobramycin, chloramphenicol, erythromycin and aztreonam) from 12 different classes (aminoglycosides, penicillins, quinolones, carbepenems, cephalosporins, polymyxins, glycopeptides, tetracyclines, aminoglycosides, amphenicols, macrolides and monobactams). Analysis of susceptibilities of the wild-type, PAA2760 and PAA2760 harbouring the pAA2760WT plasmid strains to these antibiotics was performed using the Kirby–Bauer and MIC methods (Andrews, 2001; Traub & Leonhard, 1994). Comparison of the zone of inhibition on disk diffusion for PAO1 and PAA2760 showed no significant statistical difference (Fig. 3).

Interestingly, it was observed that when the PAA2760 strain expressed wild-type OprQ, from the pAA2760WT plasmid, there was a reproducible increase in sensitivity to gentami-
cin, neomycin and meropenem (Fig. 3). When we assayed for antibiotic resistance using the MIC method, the same sensitivity phenotype was observed for the antibiotics colistin, imipenem, tetracycline and tobramycin when wild-type OprQ was placed in trans (Fig. 4). This suggests that increased expression and outer membrane localization of OprQ lead to the repression of proteins required for P. aeruginosa resistance to these antibiotics.

**Determination of Fn-binding activity**

The binding of human Fn and its relationship to infection for outer membrane proteins of *P. fluorescens* have been established. A total of six *P. fluorescens* Fn-binding outer membrane proteins (FnBPs) have been identified (Rebière-Huët et al., 2002). One of these proteins, identified as a 44 kDa outer membrane protein, is homologous to the *P. aeruginosa* outer membrane protein OprQ (Jaouen et al., 2006). Studies presented here have excluded OprQ from a role in nutrient uptake and resistance to many classes of antibiotics. However, it remains possible that OprQ is indirectly involved in *P. aeruginosa* sensitivity to certain antibiotics. Therefore, based on the reports of *P. fluorescens* and the similarity of OprQ to these FnBPs, we hypothesized that OprQ could play a role in *P. aeruginosa* binding to the extracellular matrix via Fn. In order to test the ability of *P. aeruginosa* to bind plasmatic Fn, we compared wild-type PAO1 with the PAO1 ΔoprQ strain PAA2760. Addition of whole-cell *P. aeruginosa* PAO1 to plates coated with human Fn resulted in adsorption (Fig. 4). Upon addition of PAA2760 to Fn in vitro, there was a significant drop, 88-fold, in the ability of *P. aeruginosa* to adhere to the extracellular matrix protein (Fig. 4). The introduction of the plasmid pAA2760WT into PAA2760 led to a 41-fold

\[\text{Fig. 3.} \quad P. \text{ aeruginosa} \text{ strains PAO1, PAA2760 (ΔoprQ) and PAA2760 pAA2760WT (oprQ\textsuperscript{+}) and the effect of antibiotics on growth. (a) Kirby–Bauer disk diffusion assay; cells were grown overnight at 37 °C in LB medium, standardized using the 0.5 McFarland standard, and spread onto Mueller–Hinton agar plates. (b) MIC; P. aeruginosa strains were grown in LB broth overnight at 37 °C with shaking. The growth density was adjusted to equal the 0.5 McFarland standard and cells were incubated with antibiotic for 18 h at 37 °C. Asterisks indicate statistical significance between PAO1/PAA2760 and PAA2760 + pAA2760WT, as determined by ANOVA (Tukey's post test, SYSTAT).}\]
**DISCUSSION**

In this study, we provide evidence that the *P. aeruginosa* OprQ protein, a member of the OprD superfamily, does not function in roles common to this class of outer membrane proteins. The regulation of oprQ expression may be in dual regulation with other proteins, possibly Oprs that are specifically involved in nutrient uptake and resistance to antibiotics, since the PAO1 ΔoprQ strain displays an increased growth rate under stress conditions. Furthermore, it was observed that the overexpression of OprQ could lead to increased sensitivity to certain classes of antibiotics. This suggests that expression of OprQ could be tied to the regulation of optimal growth characteristics for *P. aeruginosa* that favour the prevailing environmental condition. A model has been proposed for the outer membrane protein OmpC in *E. coli* whereby its transcriptional activation is reciprocal to that of the *ompF* gene (Ozawa & Mizushima, 1983). Early studies described this regulatory phenotype as being closed. Under conditions that favour upregulation of the *E. coli ompC* gene, OmpF expression is decreased (Schnaitman & McDonald, 1984). Likewise, when *ompF* transcription is activated there is a reciprocal repression of the *ompC* gene. This phenotype is also apparent when a mutation in OmpF is created in *E. coli*. The expression of OmpC in this background is derepressed (Ozawa & Mizushima, 1983). It is now understood that this reciprocal regulation is controlled by the transcriptional factor OmpR (Yoshida *et al.*, 2006). It has been speculated that this type of gene regulation could be widely utilized by prokaryotes (Schnaitman & McDonald, 1984). Likewise, the increased sensitivity to certain antibiotics may be controlled at the transcriptional level. Seven clinical isolates of *P. aeruginosa* from a hospital in the USA have been found to overexpress the *mexXY* genes (Woter *et al.*, 2004). In all seven cases, the transcription of the oprD gene was repressed, resulting in a decrease in outer membrane OprD (Woter *et al.*, 2004). The data presented here seem to suggest that the regulation and expression of OprQ are similar to those of the systems that control OmpC and OprD. Upon entrance into the infection site, stress conditions encountered by *P. aeruginosa* may lead to an increased expression of OprQ and enhanced binding to host tissue via Fn. This would be in conjunction with a decrease in growth rate, a phenotype that could aid in this organism’s ability to survive in the host.

The effect of OprQ on the expression of *P. aeruginosa* proteins may extend beyond those involved in metabolism, growth and antibiotic sensitivity. In addition to causing the effects previously discussed, OprQ appears to have an effect on the production of *P. aeruginosa* pyocyanin. Previous studies on pyocyanin have revealed that this secreted phenazine is important in *P. aeruginosa* disease. It has been associated with sepsis in burns (Muller *et al.*, 2009), damage to ciliary function (Lau *et al.*, 2004), apoptosis (Usher *et al.*, 2002), inactivation of vacuolar ATPase (Ran *et al.*, 2003) and damage to lung tissue (Lau *et al.*, 2004). In both acute and chronic models of respiratory infection, Lau *et al.* (2004) demonstrated that *P. aeruginosa* virulence was maximal only with the expression of pyocyanin. This is in keeping with a recent finding that *P. aeruginosa* pyocyanin inhibits the respiratory dual oxidase-thiocyanate-lactoperoxidase system, thus resulting in a reduced killing of *P. aeruginosa* by the human bronchial epithelial cells and increased survival in the host lung (Rada *et al.*, 2008). Inactivation of the oprQ gene in *P. aeruginosa* strain PAO1 yielded an increase in pyocyanin production (data not shown). As shown in Table 2, quantification of...
pyocyanin from PAA2760 by $A_{530}$ revealed at least a threefold increase over *P. aeruginosa* PAO1 (0.05 vs 0.15). Data presented here seem to suggest that the early expression of OprQ on the outer membrane of *P. aeruginosa* may be important for colonization. However, upon establishing disease and the formation of an environment that favours diminished expression of OprQ, pyocyanin production may be increased. This would allow for the expression of the full complement of virulence factors and the establishment of more substantial disease. Further investigation into the relationship between OprQ and pyocyanin production will be required to determine the exact interaction.

Most pathogens have been reported to bind host tissue via the protein Fn, which aids in colonization and infection (Joh et al., 1999; Rebière-Huët et al., 1999). The expression of Fn in epithelial cells has been positively correlated with the degree of injury in affected tissues (Roman et al., 2006). It is possible that the damaged cells of patients that express high levels of Fn provide a means for *P. aeruginosa* to adhere to and colonize the patient. In addition, it has been demonstrated that in the host respiratory epithelium, the innate mechanisms that protect against invading pathogens can be compromised when levels of iron are altered (Ganz, 2009; Porto & De Sousa, 2007). It is thought that the decreased level of iron in the respiratory tract is important as an innate mechanism against infection (Ganz, 2009). In this environment, for a true opportunistic pathogen such as *P. aeruginosa*, the ability to overcome the iron-reduced condition is crucial. The upregulation of virulence factors, especially in the initial stage of infection, would aid in *P. aeruginosa* colonization in this stressful host environment. This hypothesis is in agreement with the induction of the oprQ gene as presented in this study. We have determined that under conditions of reduced iron and magnesium, such as those described above, OprQ expression increases. Upon activation of oprQ, *P. aeruginosa* adherence to the host extracellular matrix would be enhanced. This phase of colonization to host tissue would lead to further tissue damage and the subsequent increased expression of Fn and thus more *P. aeruginosa* binding. This suggests that OprQ would be an important virulence factor involved in *P. aeruginosa* infections.
