Quantitative Analysis of the Gram Reaction

BY F. WENSINCK AND JOHANNA J. BOEVÉ

Medical Biological Laboratory of the National Defence Research Council T.N.O.,
Rijswijk-ZH, Netherlands

SUMMARY: The crystal violet and iodine uptake by suspensions of *Staphylococcus aureus* and *Escherichia coli* was determined. It was found that equal amounts of intracellular dye-iodine complex were formed in these micro-organisms. The molar ratio dye to iodine was 1:2. The extractability of this complex with methanol and ethanol was compared with the relative solubility of dye-iodine precipitates. Results with *E. coli* suggest that the solvents pass freely into the cells and decolorize them after dissociation of the dye-iodine complex. Gram-positive micro-organisms may be arranged in a number of groups according to their extractability pattern with regard to the complex. These patterns suggest the presence of interaction between the cells and ethanol. This interaction may be located at the cell wall.

The elucidation of the mechanism underlying the Gram reaction seems to be complicated by a lack of quantitative information on the successive reactions leading to differentiation. The uptake of primary stain by bacterial suspensions has been studied in some detail, but the results are divergent. Moreover, the suspensions used were, with a few exceptions, killed by heat or fixatives which are likely to have affected the staining properties. The interpretation of the effects of iodine treatment and decolorizing agents is largely based on qualitative data obtained with heat-fixed smears; as appears from the careful compilation of the literature by Bartholomew & Mittwer (1952), these data have thus far given little information on the mechanisms involved. The object of the present work was to establish essential features of Gram-positivity and Gram-negativity. Quantitative data were collected on primary stain and iodine uptake by bacterial suspensions. The effects of fixation and of decolorizer concentration on the Gram reaction were also studied. It was found that suspensions could easily be differentiated without counter-stain; this step was therefore omitted in the procedure which consisted in staining with crystal violet, treatment with iodine and differentiation with ethanol.

METHODS

Organisms. The strains used included the Gram-positive species *Staphylococcus aureus*, *Streptococcus faecalis*, *S. lactis*, *Diplococcus pneumoniae* type II, *Lactobacillus arabinosus*, *L. plantarum*, *Bacillus cereus*, *B. subtilis*, *Clostridium welchii* type A, *Saccharomyces cerevisiae*; Gram-negative organisms included *Escherichia coli*, *Aerobacter aerogenes*, *Paracolobactrum* sp., *Pseudomonas fluorescens*, *Salmonella enteritidis*, *Serratia marcescens*.

Culture media. *Staphylococcus aureus*, *Streptococcus faecalis*, *S. lactis*, *Bacillus cereus*, *B. subtilis* and the Gram-negative rods were grown in a medium...
containing 1% (w/v) Difco peptone, 0.3% Difco meat extract, 0.5% NaCl and 1% glucose. Shake cultures were incubated for 16 hr. at 32°C. *Diplococcus pneumoniae* was cultivated for 16 hr. at 37°C in beef heart infusion broth containing 1% Difco peptone, 0.5% NaCl and 0.1% glucose. *Clostridium welchii* was grown in a cooked-meat medium prepared from minced horse meat; cultures were incubated for 16 hr. at 37°C. Stephenson & Rowatt medium (1947) was used for lactobacilli, which were cultivated for 48 hr. at 25°C.

**Bacterial suspensions.** After incubation, organisms were centrifuged down, washed with distilled water and resuspended in distilled water. *Saccharomyces cerevisiae* suspensions were prepared from fresh commercial baker’s yeast. The final aqueous suspensions were adjusted to a concentration of c. 8.5 mg. dry wt./ml. with the aid of a nephelometer (Evans Electroselenium Ltd.; EEL) and dry weight/turbidity reference curves. The suspensions were adjusted to pH 7.1–7.2, unless otherwise stated.

**Dry weight and total nitrogen determinations.** Dry weights were obtained by drying 1 ml. samples of the suspensions at 110°C to constant weight. Total N determinations were performed by the Kjeldahl technique.

**Gram reaction.** Crystal violet (Gurr, Michrome brand, purity c. 85%) was used as the primary stain. The solution in distilled water contained 0.96 mg. dye/ml., corresponding to 0.82 mg. crystal violet and 0.745 mg. crystal violet cation; stock solutions were adjusted to pH 7.1. Gram’s iodine was prepared by dissolving 1 g. iodine and 2 g. potassium iodide in a small volume of distilled water; the resulting solution was diluted to a final volume of 300 ml. In the routine Gram-reaction procedure with bacterial suspensions, 96% (v/v) ethanol in water was used for differentiation.

The primary stain uptake was determined as follows. Two ml. of the crystal violet solution were added to different amounts of bacterial suspension to a total volume of 5 ml. The mixtures were left for 10 min. at room temperature and centrifuged at 3000 rev./min. for 10 min. The dye concentration of the supernatant fluid was estimated by measuring the extinction of suitable dilutions in 2% (w/v) of dipotassium phosphate by a Gallenkamp direct reading photo-electric colorimeter with an Ilford 625 filter and comparing with a calibration curve of the dye solution. The dye uptake of the organisms was computed from the difference in dye concentration between the original staining solution and the supernatant fluid. For the determination of the retention of absorbed dye, the stained sediments were suspended in 5 ml. of distilled water or the 96% (v/v) ethanol solution. One wash with water and three washes with the ethanol solution were sufficient, since further washing did not remove any more dye. The sediments after washing with water were resuspended in 3 ml. distilled water and mixed with 2 ml. iodine solution. The mixtures were left for 10 min. at room temperature and centrifuged. The sediments were washed three times with 5 ml. of the ethanol solution; the dye concentrations in the ethanol washes were determined after addition of one drop of 0.1 N- Na₂S₂O₃ solution to the dilution of supernatant fluid in phosphate solution in order to reduce iodine. In a small series of comparative experiments absolute methanol instead of ethanol was used for differentiation.
Quantitative analysis of Gram's reaction

Analysis of crystal violet-iodine complexes. The composition of precipitates resulting from the interaction of crystal violet and iodine solutions was determined by measuring crystal violet and iodine concentrations in the supernatant fluid obtained by centrifugation of the mixtures.

Graded amounts of the iodine solution used in the Gram reaction were added to a series of centrifuge tubes containing 2 ml. crystal violet solution (\( \sim 1.49 \) mg. dye-cation); the total volume was 5 ml. The tubes were left at room temperature for 10 min. and centrifuged for 10 min. at 6000 rev./min. The supernatant fluid was analysed for crystal violet in the usual way; free iodine was titrated with 0.01 N-\( \text{Na}_2\text{S}_2\text{O}_3 \) solution.

Iodine uptake by bacterial suspensions stained with crystal violet. To a series of centrifuge tubes containing 1 ml. bacterial suspension graded amounts of Gram's iodine solution were added. Free iodine in the supernatant fluids obtained by centrifugation for 10 min. at 6000 rev./min. was titrated with a 0.01 N-\( \text{Na}_2\text{S}_2\text{O}_3 \) solution. The same procedure was applied to suspensions (1 ml.) stained with crystal violet and washed with distilled water. The amount of crystal violet taken up by the suspensions was varied by using crystal violet solutions of different strength. The values for free iodine at various concentrations of iodine in excess obtained with stained and control suspensions were plotted against amounts of iodine added to the suspensions. From the resulting curves the difference between iodine uptake by stained and control suspensions was calculated.

Effect of ethanol concentration on the retention of crystal violet and crystal violet-iodine complexes. The retention of crystal violet was determined by washing stained sediments three times with 5 ml of 10-100 % (v/v) ethanol solutions in water and analysing the supernatant fluids for crystal violet. For the determination of the retention of the complex between crystal violet and iodine, the gram reaction as outlined before was performed in a series of centrifuge tubes up to the decolorizing step. The washed sediments were resuspended in 5 ml of 50-100 % (v/v) ethanol in water; three washes with the ethanol solution were made. The dye concentration in the supernatant fluids was determined in the usual way; 1 drop of a 0.1 N-\( \text{Na}_2\text{S}_2\text{O}_3 \) solution was added to the dilution in dipotassium phosphate solution.

Relative solubility of the crystal violet-iodine complex in alcohol. The extractability of the crystal violet-iodine complex from bacteria was compared with the relative solubility of this complex in 50-100 % (v/v) ethanol or methanol solutions in water. Quantities of crystal violet-iodine precipitate, approximately equal to the amount of dye-iodine complex formed in Gram-stained suspensions and containing 1.49 mg. dye-cation, were washed with distilled water and resuspended in 5 ml. portions of 50-100 % (v/v) alcohol in water solutions; washing was repeated three times and the amounts of crystal violet dissolved were determined as indicated before. The solubility figures thus obtained would not necessarily agree with those resulting from standard procedures.
RESULTS

Influence of pH value on crystal violet uptake

Fig. 1 illustrates the results obtained with *Staphylococcus aureus* and *Escherichia coli* suspensions and crystal violet solutions adjusted at pH values varying from 2 to 9. The crystal violet uptake by both *S. aureus* and *E. coli* suspensions was greatly influenced by the pH value and reached a maximum at pH 7–8. Suspensions and crystal violet solutions used in the Gram reaction were henceforth adjusted to pH 7.1–7.2.

Maximum of crystal violet uptake

When a bacterial suspension was added to a given volume (2 ml.) of a crystal violet solution, the crystal violet uptake increased with the amount of suspension used; it reached a maximum of approximately 90% (Fig. 2). The results presented in Fig. 2 are mean values obtained with 12 *Staphylococcus aureus* and *Escherichia coli* suspensions. They show a striking similarity between a Gram-positive and a Gram-negative organism in the pattern of crystal violet uptake. The crystal violet uptake by 0.5 ml. of the suspensions was not increased by doubling or tripling the strength of the crystal violet solution. Data concerning the maximal crystal violet uptake are summarized in Table 1. It is concluded from these data that *S. aureus* and *E. coli* absorb comparable amounts of crystal violet at pH 7.1.

Retention of crystal violet

On washing the stained organisms with distilled water only small amounts of crystal violet were found in the supernatant fluid after centrifugation; with 96% (v/v) ethanol in water, however, the bulk of dye was extracted (Table 2). It will be noted that the ethanol solutions decolorized Gram-positive and Gram-negative cells to the same extent.

Effect of iodine treatment on crystal violet retention

Suspensions of Staphylococcus aureus and Escherichia coli were subjected to the Gram procedure up to the stage of treatment with the counter stain and omitting, as usual, the fixation step. The results are summarized in Table 3. They clearly indicate that a Gram differentiation can be obtained with unfixed bacterial suspensions.

The residual colour of the suspensions corresponded to that of heat-fixed smears stained by the usual Gram procedure (counter-staining omitted). From Tables 2 and 3 it is apparent that the iodine treatment is essential for differentiation.

In a small series of experiments to compare the decolorization by different alcohols, iodine-treated suspensions were washed with ethanol or methanol solutions. The results listed in Table 4 show that methanol decolorizes Gram-positive as well as Gram-negative organisms. This effect could not be attributed to a difference in the solubility of the crystal violet-iodine complex in these alcohols. As appears from Fig. 5, the complex dissolves more readily in ethanol than in methanol solutions.
Analysis of crystal violet-iodine complexes

On addition of iodine to crystal violet solutions a flocculent precipitate appears which can easily be removed by centrifugation; in the presence of an excess of iodine, however, a rather stable suspension is formed of small dye particles which are difficult to spin down. The supernatant fluids obtained on centrifugation of crystal violet-iodine mixtures prepared by adding varying quantities of Gram's iodine solution (3·18 mg. iodine/ml.) to constant volumes of a crystal violet solution (2 ml.) were analysed for crystal violet and free iodine. The results are indicated in Fig. 3, which shows that crystal violet was completely precipitated by 0·325 ml. iodine solution. The crystal violet solution contained 1·49 mg. dye cation which was precipitated by 0·325 \times 3·18 mg. = 1·03 mg. iodine. The weight to weight ratio of crystal violet to iodine in the precipitate (1·49: 1·03 = 1·44) indicates equimolarity. Thus, at the iodine concentration indicated the precipitate consists of equal numbers of crystal violet cations and iodine molecules. However, as may be seen from the results in Fig. 3, the iodine concentration could be doubled without iodine appearing in the supernatant fluid. The ratio of crystal violet cations to iodine molecules in the precipitate at this high iodine concentration is therefore 1:2. It thus appears that two species of crystal violet-iodine complexes are formed, their abundance in any precipitate depending on the ratio between the concentrations of dye and iodine in the original mixture.

\[ \text{Crystal violet-iodine complex in bacteria} \]

Determinations of iodine uptake showed that more iodine is taken up by stained than by unstained bacteria. By varying the amount of dye absorbed by the suspension a relationship between extra iodine uptake and dye ab-
Quantitative analysis of Gram's reaction

sorbed could be demonstrated. This is shown in Fig. 4 which illustrates results obtained with *Staphylococcus aureus* and *Escherichia coli*. The mean ratio of crystal violet:extra iodine was 0.76; this value corresponds to one crystal violet-cation for two iodine molecules taken up, and agrees well with the dye-iodine proportion occurring in precipitates formed in the presence of an excess of iodine. It is clear from these results that iodine treatment of stained suspensions of a Gram-positive and a Gram-negative organism results in the formation of presumably identical dye-iodine complexes.

**Fig. 4.** Relation between crystal violet and extra iodine uptake by suspensions of *Staphylococcus aureus* (●) and *Escherichia coli* (×).

**Effect of the ethanol concentration on the extractability of the crystal violet-iodine complex**

It was concluded from the above results that the differences between the extractability of dye-iodine complexes from Gram-positive and Gram-negative organisms might be due to differences in the interaction of the cells with the solvent. Early in the literature reports were published showing that the addition of water to ethanol increases decolorization. This effect was studied in the present work. Suspensions of Gram-positive or Gram-negative organisms were stained with crystal violet and treated with iodine; the extractability of the dye-iodine complex by different concentrations of ethanol was determined in the usual way and compared with the relative solubility of dye-iodine precipitate in these solvents; this is illustrated in Fig. 5.

The mean extractability curves obtained with *Escherichia coli* and other Gram-negative organisms show that extraction of the dye complex by 80 to 100 % (v/v) ethanol in water is nearly complete (Fig. 6). There is a close correlation between the curves in Fig. 6 and the solubility curve of the dye-iodine precipitate (Fig. 5). This correlation suggests that ethanol passes freely in and out of these cells. Dissociation of the dye-iodine complex is followed
by a distribution of the intracellular crystal violet over the total volume of ethanol solution, resulting in decolorization.

The results obtained with Gram-positive organisms were completely different (Fig. 7), and conformed to the solubility curve of the dye-iodine precipitate (Fig. 5) up to a certain concentration of ethanol. Beyond this critical concentration, which varies for different groups of Gram-positive organisms, a sharp decrease of extractability occurs. It is seen from the curves that organisms which are known to be strongly Gram-positive show low maxima of extractability.

![Graph 5](image-url)

**Fig. 5**

**Fig. 6**

In Fig. 8 maximum values of crystal violet extraction have been plotted against the corresponding ethanol concentrations. The distribution of the maxima along the relative solubility curve of the crystal violet-iodine precipitate suggests that the absolute value of a maximum for a given organism depends on the ethanol concentration at which it is reached. According to the strength of the ethanol solution required for maximal extraction the organisms studied may be arranged in the following sequence of Gram-positivity: yeast, spore-forming organisms, lactobacilli, micrococci, streptococci.

When the pretreatment with iodine of suspensions of *Staphylococcus aureus* and *Escherichia coli* was omitted the extraction pattern of the dye by varying concentrations of ethanol was similar for both organisms. Figure 9 shows the extractability of crystal violet and the crystal violet-iodine complex as a function of the ethanol concentration. The inability of high concentrations of ethanol to extract dye which it is suggested is a characteristic of Gram positivity, clearly depends on pretreatment with iodine.
Quantitative analysis of Gram's reaction

From the above experiments it is apparent that perfect Gram differentiation may be obtained with native bacterial suspensions. It was therefore concluded that fixation plays no essential role in the Gram reaction. Nevertheless, fixation has definite effects on the primary stain uptake by suspensions. In a small series of experiments, suspensions of Staphylococcus aureus and...
Escherichia coli were heated in a boiling-water bath for periods from 30 min. to 16 hr. This treatment, involving a considerable loss of cell material (consisting mainly of ribonucleic acid), leads to a decrease of the uptake of crystal violet. Washing with distilled water, however, restored the capacity to absorb dye of the heated organisms to that of the native suspension; Gram reactions on these washed suspensions gave normal results. The same applies to suspensions treated with 96% (v/v) ethanol-ether (1:1), a mixture used for the fixation of slide preparations. Fig. 10 illustrates the results of these experiments.

**DISCUSSION**

The results of our experiments on crystal violet uptake (Fig. 2 and Table 1) show that equal amounts of dye are taken up by standardized native suspensions of a Gram-positive and a Gram-negative organism. The values calculated as mg. dye cation/mg. dry weight or mg. bacterial N agree well with the data of Bartholomew & Finkelstein (1954) for heat-killed Staphylococcus aureus and Escherichia coli. From a few experiments Kennedy & Barbaro (1958) concluded that more crystal violet was taken up by Gram-positive than by Gram-negative organisms; a Gram-variable corynebacterium assumed an intermediate position. However, the figures reported by these authors (Barbaro & Kennedy, 1954) for the uptake of crystal violet are widely spread, according to them because of many variables. Finkelstein & Bartholomew (1956) drew attention to the decolorizing effect of the buffer solutions used by Barbaro & Kennedy and concluded that no correlation between Gram-character and crystal violet uptake exists when suspensions are washed with distilled water. As no difference in crystal violet uptake was found between
Quantitative analysis of Gram's reaction

*S. aureus* and *E. coli* at various pH values (Fig. 1) it seems probable that the Stearn & Stearn concept (1924) which correlates Gram character with dye uptake capacity should be abandoned. This concept is essentially based on presumed differences between iso-electric points of Gram-positive and Gram-negative cells. These differences could not be demonstrated by electrophoresis (Harden & Harris, 1953).

A simple explanation of the effect of iodine on the extractability of crystal violet from Gram-positive and Gram-negative organisms by 96% (v/v) ethanol in water (Tables 2 and 3) might be a difference in the interaction between crystal violet and iodine in the two groups. This possibility, however, seems to be ruled out by the results of experiments on iodine uptake by stained suspensions; these showed that the dye-iodine complex in both *Staphylococcus aureus* and *Escherichia coli* contains two molecules of iodine/dye cation (Fig. 4) and corresponds to crystal violet-iodine precipitates formed in the presence of excess iodine (Fig. 3). The extractability of the dye-iodine complex from Gram-negative organisms seems to be merely a function of its solubility. The curves (Fig. 6) suggest that rapid penetration of ethanol occurs. The extractability from Gram-positive organisms however parallels the solubility only up to a critical concentration of ethanol. Beyond this concentration the extractability is considerably decreased (Fig. 7). This may be due to a decrease of penetration or to interference with the outward diffusion of the solvent. These processes were studied in heat-fixed smears stained with crystal violet and treated with iodine. In *S. aureus* smears immersed in 80% (v/v) ethanol in water solution decolorization was preceded by a colour change from black to blue resulting from dissociation of the dye-iodine complex. Immersion in absolute ethanol was not followed by colour changes, indicating that no dissociation occurred. It was concluded from this observation that in Gram-positive micro-organisms the penetration is impeded by high concentrations of ethanol.

Iodine treatment is essential for the demonstration of decreased penetration of the solvent. Fig. 9 illustrates the importance of iodine treatment and ethanol concentration in the Gram-differentiation. It is seen that comparable amounts of the dye-iodine complex are extracted from *Staphylococcus aureus* by 50% (v/v) aqueous and absolute ethanol. It may be concluded therefore that the final intra-cellular concentration of ethanol is c. 50% in both cases. The curves show that the extractability of crystal violet in the absence of iodine is nearly complete at this concentration of ethanol. Clearly, the function of iodine is to lower the solubility of the absorbed dye to a critical level at which it is very susceptible to the concentration of the solvent. This supposition finds support in the demonstration that suitability of basic dyes for the Gram reaction depends partly on the solubility of their iodine complexes in ethanol (Bartholomew & Mittwer, 1951). Specific effects of solvents however are important. Thus, methanol was found to decolorize both Gram-positive and Gram-negative organisms (Table 4) in spite of a lower solubility of the crystal violet-iodine precipitate in this solvent than in ethanol (Fig. 5).
The nature of the substrate in Gram-positive organisms which interacts in a characteristic way with ethanol and ethanol-water mixtures is unknown. It was concluded from experiments with fixed suspensions (Fig. 10) that this substrate is highly thermostable. Moreover, Gram-reactions produced normal results with suspensions of Staphylococcus aureus pretreated with solvents which were shown to decolorize S. aureus completely (methanol, 80% (v/v) ethanol in water). It is therefore concluded that solvent interactions with Gram-positive material are reversible. They are likely to occur in the cell wall, known from early experiments (Burke & Barnes, 1929) to play a major role in the Gram reaction.

From these considerations it appears that a study of cell-wall properties and particularly of interactions with organic solvents will provide much more information on Gram-positivity than will attempts to isolate Gram-positive cell material. Crystal violet stains almost every type of cell and forms intracellular complexes with iodine which have not been shown to be associated with a particular cell component. The fact that this complex cannot easily be extracted from a small fraction of cell types may be related to the characteristic structure of their cell walls. Some of the prominent features of Gram-positive cell walls are their low lipid content (Salton, 1953) and the presence of glycerophosphate which may be part of a lipid-glycerophosphate-protein cell-wall component (Mitchell & Moyle, 1951, 1954). The effect of glycerophosphate removal on Gram-positivity which has been reported by Mitchell & Moyle (1950) remains to be studied in detail.
