The Effect of Molybdenum Deficiency on the Catalase and Peroxidase Content of Neurospora crassa

By D. J. D. NICHOLAS

A.R.C. Unit of Plant Nutrition (Micronutrients), Long Ashton Research Station, University of Bristol

SUMMARY: Catalase and peroxidase were markedly decreased in quantity in molybdenum-deficient felts of Neurospora crassa. Addition of molybdenum aseptically and in vivo to mats deficient in molybdenum restored the activities of the two enzymes and the yield of mycelium to the amounts in the control treatments. Infiltration of hydrogen peroxide to growing felts, deficient in molybdenum, after 3 days of growth, resulted in a partial reconstitution of catalase to 18% and peroxidase to 50% of the control levels after a further 2 days growth but the weight of mycelium remained unchanged. There was no positive correlation between the activity of either enzyme at various stages of purification and its molybdenum content as determined by a radioassay method. The purified enzymes were not activated by molybdenum. The effect of molybdenum deficiency on the two iron-containing enzymes is probably indirect, resulting from a decrease in the activity of molybdenum-dependent flavoproteins which produce hydrogen peroxide, the common substrate for catalase and peroxidase.

In recent years molybdenum has been shown to be essential for the metabolism of some micro-organisms, higher plants and animals. Molybdenum is a constituent of nitrate reductase found in some bacteria (Nicholas & Nason, 1954c), in fungi (Nicholas, Nason & McElroy, 1954; Nicholas & Nason, 1954a, b), and in green plants (Nicholas & Nason, 1955). During the enzymic reduction of nitrate, molybdenum undergoes a valency change involving Mo$^{6+}$ and Mo$^{5+}$ (Nicholas & Stevens, 1955). When ammonium ion is the only source of nitrogen, however, nitrate reductase does not usually form in plants and the molybdenum requirement, although considerably decreased, is not completely eliminated. Thus molybdenum appears to be required for metabolic processes other than for the reduction of nitrate. The present paper amplifies a preliminary publication in which it was shown that a deficiency of molybdenum in Neurospora crassa, wild type 146, decreased the amounts of catalase and peroxidase obtained in cell-free extracts of the mycelial felts (Nicholas, 1956). It is also indicated that the decrease in amount of the two iron-containing enzymes is probably caused by a diminution of hydrogen peroxide production in Mo-deficient felts.

METHODS

Organism. Neurospora crassa, microconidial, wild type 146, was kindly supplied by Dr William D. McElroy (McCullum-Pratt Institute, Johns Hopkins University, Baltimore, U.S.A.). The fungus maintained at 30° on nutrient agar slopes (20 g. agar, 5 g. yeast extract, 5 g. malt extract/litre of
culture medium) was subcultured weekly to ensure that it made vigorous growth.

Culture medium. The fungus was grown in the following basal liquid medium: sucrose, 20 g.; \( \text{NH}_4\text{NO}_3 \), 2 g.; Na tartrate, 1 g.; \( \text{KH}_2\text{PO}_4 \), 3 g.; \( \text{MgSO}_4\cdot7\text{H}_2\text{O} \), 0.5 g.; \( \text{NaCl} \), 0.1 g.; \( \text{CaCl}_2 \), 0.1 g.; biotin, 5 \( \mu \)g.; \( \text{FeCl}_3\cdot6\text{H}_2\text{O} \), 9.6 \( \times \) 10\(^{-4} \) g.; \( \text{ZnSO}_4\cdot7\text{H}_2\text{O} \), 8.8 \( \times \) 10\(^{-3} \) g.; \( \text{CuCl}_2\cdot2\text{H}_2\text{O} \), 2.7 \( \times \) 10\(^{-4} \) g.; \( \text{MnCl}_2\cdot4\text{H}_2\text{O} \), 7.2 \( \times \) 10\(^{-5} \) g.; \( \text{Na}_2\text{MoO}_4\cdot2\text{H}_2\text{O} \), 1.2 \( \times \) 10\(^{-5} \) g.; glass-distilled water to 1 l.; pH 4.8.

Removal of molybdenum from the basal medium. Molybdenum was effectively removed from a solution of the macronutrients including sucrose adjusted to pH 2.0 with 6N-HCl, by the copper sulphide co-precipitation method (Nicholas & Fielding, 1951; Nicholas, 1952). The pH was then re-adjusted to 4.8 with pure NaOH, prepared by passing 5\% (w/v) NaOH through an Amberlite column IRA 400 (OH), (8 ft. by 2 in.) which was well washed with glass-distilled water before use. The micronutrient elements which were added to the media after the purification were spectrographically pure reagents obtained from Johnson and Matthey, Hatton Garden, London, E.C. 1. Biotin was obtained in ampoules containing 25 \( \mu \)g. biotin from the Ashe Laboratories (Leatherhead, Surrey). The medium was dispensed in 200 ml. amounts in 1 l. Erlenmeyer flasks, inoculated with a suspension of the fungus mycelium contained in sterile glass-distilled water, and incubated in the dark at 28\(^\circ\). The cultures were shaken daily to prevent sporulation of the fungus.

Preparation of cell-free extracts. The mycelial mats from normal and Mo-deficient cultures, collected separately in Buchner funnels, and washed well in glass-distilled water, were frozen for 3 hr. at \(-17^\circ\). They were then ground in a mortar with three times their weight of cold 0.1 M-phosphate buffer (pH 7.5) and then in a Ten Broeck glass macerater (made to specification by Jencons Ltd., Hemel Hempstead, Hertfordshire) at 0\(^\circ\). The solutions were centrifuged at 2000 \( g \) for 10 min. at 4\(^\circ\). Over 90\% of each of the two enzymes was present in the supernatant solutions.

Enzyme assays. Catalase was determined in samples of the extracts by the perborate method (Feinstein, 1949); the enzyme activity being expressed as \( \mu \)mole perborate degraded/5 min./mg. protein.

Peroxidase was assayed by the method of Smith, Robinson & Stotz (1949) as the change in \( \log I_0/I \) of 0-001/min., calculated from 15 to 75 sec./mg. protein. Protein was determined by the method of Lowry, Rosebrough, Farr & Randall (1951).

Radioassay of molybdenum-99 in enzyme fractions. Carrier-free \( ^{99}\text{Mo} \), as sodium molydate, was obtained from A.E.R.E. Harwell. Ordinary sodium molybate (A.R.) was added to the tracer so that 20 \( \mu \)g. Mo was labelled with 4 \( \mu \)C \( ^{99}\text{Mo} \)/l. culture solution. The culture solutions were first freed from Mo by the method of Nicholas (1952) and then inoculated with a suspension of the fungus mycelium. After 3 days of growth, 0.8 \( \mu \)C \( ^{99}\text{Mo} \)/4 \( \mu \)g. Mo as sodium molybate contained in 5 ml. glass-distilled water, was added aseptically to each flask containing 200 ml. culture medium. After a further 2 days of incubation the felts were harvested and the enzymes extracted as described above. The two enzymes were fractionated by ammonium sulphate precipita-
Effect of molybdenum on Neurospora enzymes

Effect of molybdenum deficiency

The data in Fig. 1 show the effects of molybdenum deficiency on the content of the two iron-containing enzymes in the mycelial felts harvested after 3, 4 and 5 days of growth. The deficiencies of molybdenum in Expts. A, B and C resulted in yields of 35, 50 and 65% of the weight of the normal non-deficient felts on the 5th day on growth.

Catalase production increased in the normal felts from the 3rd to the 5th day and the amount of peroxidase was usually greater on the 4th and 5th days than on the 3rd day. The effect of molybdenum in decreasing catalase and peroxidase activity was more pronounced at the 4th and 5th days. In Expt. C, where the deficiency was less severe, catalase production was markedly decreased at the three stages of growth, whereas peroxidase was decreased on the 5th day only. Thus a deficiency of molybdenum seems to decrease production of catalase before that of peroxidase.
The fungus was grown with various quantities of Mo and the amounts of the two enzymes were determined in extracts of the felts; the results are illustrated in Fig. 2. An increase in the molybdenum content of the medium from 0 to 4 µg./200 ml. basal solution was paralleled by increased production of the two enzymes in the felts. The maximum activities were reached with 4 µg. Mo/200 ml. basal solution; the addition of 8, 16 and 32 µg. depressed the yields of the two enzymes.

![Fig. 2. Effect of different amounts of Mo in the culture solution on the yields of two iron-containing enzymes. Enzyme units as in Table 1.](image)

The effects on the weight and the production of the two iron-containing enzymes in the felts of adding Mo aseptically in vivo to normal cultures and to those deficient in Mo, after 8 days of growth, are illustrated in Fig. 3. The addition of Mo to the deficient felts resulted in a restoration of the weight to about 75% of that of the normal felts after a further 2 days of growth. The amount of catalase recovered to 85 and 75% of that in normal felts at the 4th and 5th day respectively. After addition of Mo to the deficient felts, the peroxidase activity at the 4th day exceeded the values in the control felts. On the 5th day, the peroxidase content was about 95% of that in the normal felts.

![Fig. 3. Effect of concentration of Mo on fresh weight, and catalase and peroxidase contents of Neurospora crassa.](image)
Effect of molybdenum on Neurospora enzymes

It was not possible to reconstitute the two enzymes to the normal levels by adding 0.1 or 1 µg. Mo⁶⁺ (as sodium molybdate) or Mo⁵⁺ (as molybdenum pentachloride) to homogenates of felts deficient in Mo. Mixing extracts of normal mycelial felts with those from Mo-deficient felts proved that there was neither an inhibitor in the deficient felts nor an activator in the normal ones.

Effect of hydrogen peroxide

In order to establish whether Mo-deficiency was affecting the formation of the common substrate of the two iron-containing enzymes, hydrogen peroxide in graded amounts was added aseptically to the cultures of normal and deficient felts after 2 days of growth. Treated and non-treated felts were harvested immediately and others after a further 1, 2 and 8 days growth (viz. at the 3rd, 4th and 5th days of incubation). The results for the addition of 6 mg. \( \text{H}_2\text{O}_2 \)/200 ml. culture medium is illustrated in Fig. 4. The addition of the \( \text{H}_2\text{O}_2 \) had no effect on the weight of felt of the control or the Mo-deficient cultures. On the 5th day catalase activity was partially restored (18% of normal) and peroxidase activity showed a 50% increase. There was no comparable effect in the control felts. The Mo content of the hydrogen peroxide added, determined by the bioassay method (Nicholas, 1952) was negligible. Thus no Mo was introduced in the hydrogen peroxide, as confirmed by finding no increase in the yield of Mo-deficient felts treated with this peroxide solution.

![Fig. 4. Effect of hydrogen peroxide on fresh weight, catalase and peroxidase in Neurospora crassa grown with and without Mo.](image)

Purification of catalase and peroxidase in relation to their molybdenum contents

To establish whether or not the effect of Mo-deficiency was on hydrogen peroxide production only, the two enzymes were purified and the Mo content and enzyme activity of the various fractions determined. To facilitate Mo determinations, 4 µc. \(^{99}\text{Mo}\)/20 µg. Mo were incorporated/l. culture medium. Mycelial felts grown in 4 l. labelled media were used for each fractionation. The \(^{99}\text{Mo}\) content of the various fractions were determined by radio-assay.

The results for catalase and peroxidase are given in Tables 1 and 2. The correlations between the value of \(^{99}\text{Mo}/\text{mg. protein} \) and the specific activity of

catalase or peroxidase (enzyme units/mg. protein) are illustrated in Figs. 5 and 6. It is clear that there was no positive correlation between the Mo content of either enzyme and its activity, so that molybdenum does not appear to concentrate in these enzymes as they are purified. Further, the addition of Mo⁶⁺ as sodium molybdate or Mo⁵⁺ as molybdenum pentachloride did not stimulate the activity of the purified fractions of either enzyme. Thus molybdenum seems unlikely to be a constituent of these two iron-containing enzymes.

**Fig. 5.** Relation between specific activity of catalase (units/mg. protein) and mµg. Mo/mg. protein in the various protein fractions of the fungus.

**DISCUSSION**

Although a deficiency of molybdenum depressed catalase and peroxidase activities in *Neurospora crassa*, possibly by decreasing the amount of their common substrate hydrogen peroxide, the mechanism whereby this occurs is not clear. It is known that riboflavin and flavin mononucleotide (FMN) or flavin adenine dinucleotide (FAD) react with oxygen to form hydrogen peroxide (Theorell, 1951). It has also been shown that some flavoprotein enzymes may be decreased in activity when molybdenum is deficient. Thus nitrate reductase in fungi, bacteria and green plants, which has FAD as the native flavin coenzyme, has been shown to contain molybdenum which undergoes a valence change involving Mo⁶⁺ and Mo⁵⁺ during the enzymic reduction of nitrate (Nicholas & Stevens, 1955). In *Pseudomonas fluorescens* grown at low oxygen pressure, the electron transfer system is mainly iron-dependent,
Effect of molybdenum on Neurospora enzymes

whereas under high oxygen pressures a molybdo-flavoprotein system became dominant (Lenhoff, Nicholas & Kaplan, 1956). Thus a deficiency in hydrogen peroxide in Neurospora crassa may well arise from a depletion in molybdenum-dependent flavoproteins which have the capacity to react with oxygen to form peroxides, this in turn diminishing the degree of induced formation of catalase and peroxidase.

Thanks are due to Mr C. P. Lloyd-Jones, B.Sc., for providing a counting service for the radioassay of 99Mo and to Mr G. Mabey for technical assistance. Mr G. H. Jones kindly made the photographic records.
