
The Mode of Action of Phenanthridines: The Effect of Ethidium Bromide on Cell Division and Nucleic Acid Synthesis

BY B. A. NEWTON

Medical Research Council Unit for Chemical Microbiology, Biochemical Laboratory, University of Cambridge

SUMMARY: The action of 2,7-diamino-9-phenyl-10-ethyl phenanthridinium bromide (ethidium bromide) on the parasitic flagellate Strigomonas oncopelti has been studied. The drug is irreversibly active only against growing organisms. Addition of the drug to cultures of organisms in the logarithmic phase of growth did not result in an immediate inhibition of growth but in a progressive decrease in growth rate; at least a doubling in number of organisms always occurred before multiplication finally ceased. During the period of growth in the presence of drug the deoxyribonucleic acid content of the organisms fell to half its normal value whilst the ribonucleic acid remained approximately constant. Conditions have been determined which permit the synthesis of nucleic acids and proteins by washed suspensions of S. oncopelti and the effect of ethidium bromide on these processes has been studied. The drug rapidly inhibits DNA synthesis whereas RNA and protein synthesis continue for a period of 2–3 hr. after the addition of drug. A study has been made of the uptake of 14C-labelled ethidium bromide by organisms under conditions which will or which will not permit nucleic acid synthesis. The uptake of drug is of two types: (i) an initial rapid uptake which occurs in the absence of nucleic acid synthesis and which does not affect the subsequent growth of organisms; (ii) an additional uptake by growing organisms which appears to follow the course of RNA synthesis and which results, eventually, in an inhibition of growth.

Certain phenanthridinium compounds, originally synthesized by Morgan, Walls, Browning, Gulbranson & Robb (1938), possess trypanocidal properties (Browning, Morgan, Robb & Walls, 1938) and have been used with success against Trypanosoma congoense and T. vivax infections in cattle. Walls (1945) demonstrated that high trypanocidal activity in the phenanthridine series is a property of quaternary salts containing a primary amino group in the 7- and a phenyl group in the 9-position; the activity is much increased by the presence of a second amino group, thus 2,7-diamino-9-phenyl-10-methyl phenanthridinium bromide (dimidium bromide) and the 10-ethyl analogue (ethidium bromide) are particularly effective (Watkins & Woolfe, 1952; Woolfe 1952).
Up to the present time there have been few studies of the mode of action of these compounds. Lock (1950) examined the action of dimidium bromide upon *Trypanosoma congolense* and *T. brucei* maintained in vitro and found that prolonged exposure under these conditions did not kill the trypanosomes, although some loss of infectivity was detected when drug-treated organisms were injected into animals. Chemical methods of analysis failed to show any uptake of drug by trypanosomes. Ormerod (1951a, b) showed, by histochemical techniques, that after 24 hr. contact with dimidium bromide, chromophilic granules containing ribonucleoprotein appeared in the cytoplasm of trypanosomes. He also observed that growth in the presence of dimidium bromide resulted in an increase in the number of multinuclear forms and a decrease in the number of dividing forms of trypanosomes; the motility of the organisms was unaffected. Ormerod obtained similar results with other trypanocidal drugs, including antrycide and suramin, and he postulated that these drugs prevent growth and cell division, but not nuclear division, by splitting cytoplasmic ribonucleoprotein into its constituent protein and nucleic acid. In support of this hypothesis he found that no antrycide could be detected in the nucleus of drug-treated trypanosomes by fluorescent microscopy whereas the cytoplasmic granules were strongly fluorescent, indicating the presence of drug in these structures. The slow action of these drugs, Ormerod suggested, was due to the slow rate of penetration into cells.

The antiviral and antibacterial activity of phenanthridines have been studied recently by Dickinson, Chantrill, Inkley & Thompson (1953) and by Seaman & Woodbine (1953); both groups of workers have observed that the action of these drugs can be annulled by addition of nucleic acid to the drug-containing medium. Hawking (1953), reviewing current knowledge of trypanocidal compounds, suggested that further study of the mode of action of phenanthridines and related drugs might yield information about nucleic acid metabolism in general and the role of cytoplasmic ribonucleoprotein in particular; such studies have been delayed by the difficulties encountered in the cultivation and maintenance of pathogenic trypanosomes which are sensitive to the phenanthridine drugs. The trypanosomid flagellate *Strigomonas oncopelti* would seem to be ideally suited for the investigation of these problems; it can be readily cultivated in certain peptones (Lwoff, 1937) or in a simple chemically-defined medium (Newton, 1956) and its growth under these conditions is inhibited by low concentrations of ethidium bromide. The present paper describes the growth inhibitory action of ethidium bromide on *S. oncopelti* and its effect on the synthesis of nucleic acid and protein by this organism.

**METHODS**

*Organism.* The strain of *Strigomonas oncopelti* previously described (Newton, 1957) was used.

*Conditions of culture.* Stock cultures were maintained in 5 ml. volumes of 8 % (w/v) Evans Bacteriological Peptone containing 0.5 % (w/v) sodium
chloride and 0.5 % (w/v) glucose, at an initial pH value of 7.4 (to be referred to as ‘peptone glucose medium’). The medium was sterilized by autoclaving at 15 lb./sq.in. for 20 min. Cultures were incubated at 25° and subcultured every other day. Larger batches of organisms were grown in 50 ml or 500 ml of peptone glucose medium contained in either 150 ml or 1-litre flasks; a 10 % (v/v) inoculum from a 15 hr. culture in the same medium was used and cultures were incubated with shaking in a water bath maintained at 25°.

**Preparation of washed suspensions.** Organisms were harvested by centrifugation, washed three times with a buffered salts solution containing (%. w/v): 0.9 NaCl; 0.4 KCl; 0.025 Na₂HPO₄. 2H₂O; 0.008 KH₂PO₄; trace metals as described previously (Newton, 1957), and finally suspended in this solution to give a density of c. 10⁸ organisms/ml. This suspension was diluted 1/10 during incubation under the various conditions to be described. Washed suspensions to be used for the study of nucleic acid and protein synthesis were prepared in the same way but under aseptic conditions.

**Counts of organisms.** In all experiments growth was estimated by counts; 1 ml samples of cultures were fixed with 0.05 ml. 40 % (w/v) formaldehyde in water. Routinely four counts were made on each sample in a Neubauer haemocytometer, a minimum of 300 organisms being counted in each case. Ten counts/sample were made when cultures were being examined for synchronization of division.

**Cytochemical techniques.** Smears of organisms were prepared on microscope slides, dried in air and fixed by immersion in absolute methanol for 10 min. Preparations were then stained either with May-Grunwald and Giemsa dyes or with methyl green and pyronin G as described by Jacobson & Webb (1952). As a control for the staining of deoxyribonucleoprotein by the above methods, preparations were stained by Feulgen’s method after 3 min. hydrolysis in N-HCl at 60°. In some cases fixed smears were treated with enzymes before staining; enzymes used were: crystalline protease-free ribonuclease, crystalline deoxyribonuclease (Sigma Chemical Co. U.S.A.) and crystalline trypsin (Worthington Biochemical Sales Co. U.S.A.). Enzyme solutions (0.1 %, w/v) were prepared in glass-distilled water, containing in the case of deoxyribonuclease, 0.075 M-MgSO₄. Preparations were incubated in enzyme solutions at 37° for different periods of time; in each experiment a control preparation was incubated in glass-distilled water alone.

**Temperature-induced synchronous division in cultures of Strigomonas oncopelti.** Partial synchronization of cell division was obtained by subjecting organisms, suspended in peptone glucose medium, to a series of controlled temperature shifts between 25° (the optimum growth temperature) and 5°. Suspensions containing 5 × 10⁶ organisms/ml. were maintained at each temperature for 1 hr. and the temperature cycling was continued during 18 hr. Rapid temperature shifts were obtained by means of an apparatus similar to that described by Scherbaum & Zeuthen (1955).

**Amino acid, purine and pyrimidine solutions.** Solutions (1-2 % w/v) of glycine and of the L isomers of the following amino acids were prepared: L-aspartic and L-glutamic acids, L-arginine, DL-methionine, L-lysine, DL-
Mode of action of phenanthridines

threonine, L-proline, DL-tryptophan, L-tyrosine, L-cysteine, DL-serine, DL-phenylalanine, L-histidine, L-valine, DL-alanine, L-leucine and DL-isoleucine; each solution was adjusted to pH 7.0. Solutions (0.12 %, w/v) of each of the following purines and pyrimidines were prepared: adenine, guanine, xanthine, thymine, cytosine and uracil. All these solutions were diluted 1/100 in incubation mixtures.

Incubation mixtures. Incubation mixtures in 150 ml. conical flasks contained: 0.6 ml. 20 % (w/v) glucose, 0.1 ml. of each of the amino acid solutions, 0.1 ml. of each of the six purine and pyrimidine solutions, 7.3 ml. of the buffered salts solution described, 1.2 ml. of a washed suspension of Strigomonas oncopelti prepared as above, 0.5 ml. ethidium bromide solution; where any component was omitted an equal volume of buffered salts solution was added. Flasks were closed with cotton plugs and incubated with shaking at 25°. Before the addition of washed organisms and ethidium bromide, incubation mixtures were sterilized by autoclaving at 15 lb./sq.in. for 10 min., the cotton plugs being covered with grease-proof paper to prevent loss of contents by evaporation; suspensions of organisms and ethidium bromide were then added with the usual precautions to prevent contamination. Ten ml. from the incubation mixtures were transferred to 15 ml. centrifuge tubes at the end of an incubation period and rapidly cooled to 0°. The organisms were harvested by centrifugation, washed with cold buffered salts solution and analysed for protein and nucleic acid.

Protein and nucleic acid content of organisms. Suspensions of organisms after washing were precipitated with perchloric acid to a final concentration of 0.2N. After standing for 1 hr. at 5° the precipitates were centrifuged down, washed twice with cold 0.2N-perchloric acid and then extracted three times successively with 0.5N-perchloric acid at 70° for 30 min.; 90–95 % of the total nucleic acid was extracted in the first two treatments and no further extraction took place after the third treatment. Samples of the combined extracts were taken for the determination of total nucleic acid content by measurement of absorption at 260 mμ in a Beckman spectrophotometer (Model DU); samples were also taken for the determination of deoxyribose by the diphenylamine method of Burton (1956). The residue remaining after extraction with perchloric acid represented the main protein fraction of the organisms and was either suspended in 0.75 ml. 20 % (v/v) acetone in water for radioactivity determinations, or was digested by the Kjeldahl method under the conditions described by Chibnall, Rees & Williams (1943); the ammonia collected after distillation in a Markham apparatus (Markham, 1942) was determined colorimetrically with Nessler's reagent as described by Johnson (1941).

Radioactivity measurements. Samples (0.3 ml.) of protein fractions labelled with 14C-glycine suspended in 20 % (v/v) acetone in water were placed on polythene disks of surface area 2 sq.cm.; 1 drop of 1 % (w/v) polyvinyl alcohol was added to each sample and the preparations dried in vacuo. In this way films of less than 1 mg./sq.cm. were obtained and self-absorption was less than 5 %. The 14C content of dried preparations was estimated by use of an end window Geiger-Muller tube. In experiments designed to measure the uptake
of $^{14}$C-labelled ethidium bromide by *Strigomonas oncopelti*, organisms, after harvesting from a drug-containing medium, were washed three times with cold buffered salts solution and then suspended directly in 0.75 ml. 20% (v/v) acetone in water. Samples (0.3 ml.) were then plated out as described above, but because the $^{14}$C-labelled drug had a low specific activity (0.17 mc./g.) radioactivity measurements were made on a windowless gas-flow (methane) counter operating in the proportional range as described by Taylor & Sharpe (1951). Backgrounds and samples were counted sufficiently long to give a standard error of less than 5% in all cases and counts were corrected for self absorption.

*Isotopes.* Glycine labelled with $^{14}$C in the carboxyl position was obtained from the Radiochemical Centre, Amersham; dimidium and ethidium bromides, each labelled with $^{14}$C in the 9 position in the phenanthridine ring, were the gift of Boots Pure Drug Co. Ltd., Nottingham.

**RESULTS**

*Cytochemical observations*

Growth of *Strigomonas oncopelti* for 12 hr. or more in the presence of ethidium bromide (15 µg./ml.) resulted in the appearance of refractile cytoplasmic granules which were readily seen in living organisms by phase contrast microscopy. In fixed preparations these granules were stained red by pyronin G, blue by May-Grunwald and Giemsa dyes and were Feulgen negative. Treatment of fixed smears of organisms with deoxyribonuclease did not affect the staining properties of the granules; treatment with ribonuclease resulted in a complete loss of basophilic material after 30 min. incubation at 37°C and the residual granules appeared to be weakly eosinophilic. Complete digestion of the granules was achieved by treatment of fixed preparations with ribonuclease and trypsin for 30 min. at 37°C. These findings are in agreement with the results of Ormerod (1951b) who examined the effect of dimidium bromide on *Trypanosoma equiperdum* and *T. rhodesiense* and they suggest that the granules resulting from drug treatment contain ribonucleoprotein. In contrast to Ormerod's results, no increase in the number of multinuclear forms of *Strigomonas oncopelti* resulted from growth in the presence of ethidium bromide.

*Inhibition of division by ethidium bromide*

**Effect of drug concentration.** Multiplication of *Strigomonas oncopelti* in peptone glucose medium was not immediately prevented by the addition of ethidium bromide; 70–80% increases in number of organisms always occurred after the addition of 20–200 µg. ethidium bromide/ml. to a culture containing c. $5 \times 10^6$ organisms/ml. With less than 20 µg. ethidium bromide/ml. greater increases in numbers occurred before multiplication finally stopped (Fig. 1).

**Reversibility of ethidium bromide inhibition.** When multiplication of *Strigomonas oncopelti* had ceased in the presence of ethidium bromide, it was not restarted by removal of organisms to a drug-free medium. When organisms were transferred from a drug-containing medium to a drug-free medium at
intervals before multiplication stopped, they continued to multiply, but at a decreased rate (Fig. 2). The growth rate of drug-treated organisms was related to the time they had been in contact with the drug and was found to remain constant for 3–4 generations, after which there was a gradual increase to the control growth-rate over a further two generations.

Effect of ethidium bromide on non-dividing organisms

The effect of ethidium bromide on non-dividing organisms was examined under two conditions: (a) washed organisms suspended in a buffered salts solution containing 0.5% (w/v) glucose and incubated at 25°; (b) organisms suspended in peptone glucose medium and incubated at 11°. Organisms could be incubated under either of these conditions for 10–12 hr. without any loss in motility or viability, but no division occurred nor was there any increase in the nucleic acid or protein content of organisms. Ethidium bromide (15 μg/ml) was added to suspensions of organisms incubated under conditions (a) or (b). Samples were removed at intervals during a 10 hr. incubation period and the organisms washed free from drug, resuspended in peptone glucose medium and incubated at 25°; samples from control suspensions containing no drug were treated similarly. In all cases multiplication was estimated by counts of organisms. It was found that ethidium bromide (15 μg/ml) was without effect on organisms incubated under either of the above conditions; no decrease in the growth rate of drug-treated organisms, compared with control organisms, occurred after 10 hr. contact with the drug.
Effect of ethidium bromide on synchronously dividing organisms

The slow action of ethidium bromide and the doubling in number of organisms which occurs before the multiplication of *Strigomonas oncopelti* is stopped by this drug might be due to differences in drug sensitivity of organisms at different stages in the division cycle. Only a small percentage of the total population of a culture of actively growing organisms will be in a particular phase of cell division at any one time; thus if organisms are only sensitive to ethidium bromide at one stage in the division cycle the majority of a population would be expected to divide once after the addition of drug to a culture. By using cultures in which cell division was partially synchronized it has been possible to examine the effect of ethidium bromide on a large number of organisms in approximately the same stage of cell division.

Partial synchronization of cell division in cultures of *Strigomonas oncopelti* was induced as described above. Fig. 3a shows a typical stepped growth curve obtained by these methods; the initial increase in count of organisms corresponds to the division of c. 70% of the total population in a period of time equal to about one-quarter of a normal generation time (7.5-8 hr.).

In experiments designed to test the effect of ethidium bromide on organisms in different stages of division, a 400 ml. volume of peptone glucose medium containing c. 10^8 organisms/ml. growing in partial synchrony was divided into 50 ml. samples; each sample was placed in a 150 ml. conical flask and incubated at 25°. At intervals of 2 hr. ethidium bromide (final concentration 20 µg./ml.) was added to the contents of one flask and the incubation continued for a further 2 hr. The organisms were then harvested, washed and re-suspended in drug-free peptone glucose medium and re-incubated at 25°. Multiplication was estimated by counts of organisms. The contents of one flask to which no drug had been added were harvested at the same time as samples of drug-treated organisms and were treated similarly. The curves obtained for the growth of drug-treated organisms (Fig. 3b) show that 2 hr. contact with ethidium bromide resulted in the same decrease in growth rate, regardless of the stage in cell division at the time of contact with the drug. These results show that the slow action of ethidium bromide is not due to variations in the drug sensitivity of organisms at different stages in the division cycle.

Changes in the nucleic acid content of ethidium bromide-treated organisms. Table 1 records the changes in nucleotide, ribonucleic acid and deoxyribonucleic acid content of organisms during asynchronous growth in the presence or absence of ethidium bromide. When the drug (final concentration, 20 µg./ml.) was added to a culture of initial density 2 x 10^6 organisms/ml. multiplication continued for 16 hr. and the count of organisms approximately doubled before multiplication ceased; during this time the deoxyribonucleic acid content of organisms fell progressively to half its normal value, whereas the nucleotide and ribonucleic acid content changed little.

Fig. 3a. Partial synchronization of cell division in cultures of Strigomonas oncopelti. A stepped growth curve obtained by subjecting organisms, suspended in peptone glucose medium (5 × 10⁶ organisms/ml.), to a series of controlled temperature shifts between 25° and 5°; suspensions were held at each temperature for 1 hr.; total period of temperature shifts, 18 hr.; final growth temperature 25°. Each point on the graph is the mean of 10 counts and the bars through these points represent the standard error of the mean of these determinations.

Fig. 3b. Effect of ethidium bromide on organisms dividing in partial synchrony. Ethidium bromide (20 μg./ml.) added at 2 hr. intervals to 50 ml. samples of a culture containing organisms dividing in partial synchrony. Arrows in Fig. 3a indicate the points on the growth curve at which drug was added. After 2 hr. contact with the drug organisms were harvested, washed and resuspended in drug-free peptone glucose medium. Growth was estimated by counts of organisms at intervals during 14 hr. of incubation at 25°.

Table 1. Changes in the ribonucleic acid, deoxyribonucleic acid and nucleotide content of Strigomonas oncopelti growing in the presence of ethidium bromide

Growth medium; peptone glucose. Growth temp. 25°. Inoculum = 5 × 10⁶ organisms/ml. Samples were taken at intervals from a control culture (C) and an ethidium bromide (20 μg./ml.)-containing culture (E); organisms were harvested, washed and their nucleic acid content determined as detailed in the text. The figures indicate changes in nucleotide, ribonucleic acid (both expressed as log I₆₀/I at 200 mµ./10⁹ organisms) and deoxyribonucleic acid (estimated by the diphenylamine method and expressed as log I₆₀/I at 600 mµ./10⁹ organisms) content of organisms growing in the presence or absence of drug during 24 hr.

nucleic acid and protein synthesis by washed suspensions of *Staphylococcus aureus*, found that there was an increase in the nucleic acid content of the organisms when they were incubated in the presence of glucose, a mixture of amino acids, purines and pyrimidines; little or no formation of nucleic acid occurred in the absence of amino acids or glucose. Similar results have been obtained for *Strigomonas oncopelti*; when washed organisms were incubated at 25° for 5 hr. with glucose, purines, pyrimidines and 18 amino acids the ribonucleic acid and protein content of the suspension increased by 70–80% and the deoxyribonucleic content by 35–45% (Fig. 4). The addition of ethidium bromide (20 μg./ml.) to a washed suspension incubated under these conditions resulted in a rapid inhibition of deoxyribonucleic acid synthesis whilst protein and ribonucleic acid synthesis continued for 2–3 hr. (Fig. 5).

**Uptake of 14C-labelled ethidium bromide by Strigomonas oncopelti**

**Uptake by organisms growing in peptone glucose medium.** Fig. 6 shows that the uptake of 14C-labelled ethidium bromide by organisms growing in a peptone glucose medium continued throughout the period of growth in the presence of the drug. A considerable uptake (c. 3 μg. ethidium/10⁸ organisms) occurred during the lag phase of growth, during which time there was no increase in number of organisms.

**Release of drug from organisms.** To determine whether ethidium bromide which had been bound by organisms was released again during multiplication in a drug-free medium, organisms were suspended in peptone glucose medium containing 10 μg. 14C-labelled ethidium bromide/ml. and incubated at 25° for 4 hr. Organisms were then harvested, washed and resuspended in drug-free peptone glucose medium and incubated at 25° for a further 22 hr. Samples
Mode of action of phenanthridines

were taken at intervals during this second incubation for counting the number of organisms and for the determination of 14C-labelled drug bound to the organisms. Table 2 shows that there was no significant release of 14C-labelled drug from the organisms during 22 hr. of growth in a drug-free medium.

Table 2. Uptake of 14C-labelled ethidium bromide by Strigomonas oncopelti.

Effect of growth in a drug-free medium after an initial period of growth in the presence of drug

Organisms were grown for 4 hr. in peptone glucose medium containing 10 μg. 14C-labelled ethidium bromide/mL., washed three times with drug-free peptone glucose medium and resuspended in this medium. Organisms from samples taken at intervals during a 22 hr. period of incubation at 25° were harvested, washed, suspended in 20% (v/v) acetone in water and dried on polythene planchettes for radioactivity determinations in a windowless gas-flow (methane) counter.

Uptake of 14C-labelled ethidium bromide by washed suspensions. This was studied under two conditions: (i) washed organisms suspended in buffered salts solution containing glucose, purines and pyrimidines; (ii) as condition (i) but with the addition of a mixture of 18 amino acids. Under condition (i) organisms synthesized little or no nucleic acid during 6 hr. of incubation at 25°; under condition (ii) a linear increase in the nucleic acid content of organisms occurred. Addition of a mixture of 18 amino acids to organisms incubated under condition (i) initiated nucleic acid synthesis (Fig. 7a). 14C-labelled ethidium bromide (final concentration, 10 μg./ml.) was added to organisms incubated under condition (i) and samples for radioactivity determinations were taken at intervals during a 6 hr. incubation period at 25°. It was found that drug was rapidly bound by organisms during the first 30 min. of the incubation period (c. 3 μg./10⁸ organisms) but no more drug was bound during the next 5-5 hr.; addition of a mixture of 18 amino acids to the suspension resulted in a 40% increase in the amount of 14C-labelled ethidium bromide bound by the organism. Fig. 7b records these results; the 14C-labelled drug bound by organisms is expressed as a percentage of the amount bound during 30 min. incubation under condition (i). The uptake of radioactive drug by organisms incubated under condition (ii) is also shown in Fig. 7b.

The effect of dimumidium bromide on division and nucleic acid synthesis in Strigomonas oncopelti. Similar experiments to those already described were performed with dimumidium bromide; the results showed that this drug has an effect similar to ethidium bromide on the division of Strigomonas oncopelti and on the synthesis of nucleic acid and protein by this organism.

The uptake of radioactive drug expressed as % of increase in the amount bound by organisms during 80 min. incubation under condition i. Incubation temp, 25°.

DISCUSSION

Cytochemical studies led Ormerod (1951b) to propose that dimidium bromide inhibited the growth of trypanosomes by splitting cytoplasmic ribonucleoprotein into its constituent ribonucleic acid and protein. This hypothesis does not provide an adequate explanation of the results described in the present paper; it would be expected that a compound which caused the disorganization of nucleoprotein by the cleavage of electrostatic bonds would be active against non-growing organisms, but this was found not to be the case.

It is possible to advance a number of explanations for the slow action of ethidium bromide and for the approximate doubling in number of organisms which occurs before the multiplication of *Strigomonas oncopelti* is stopped by this drug. First, variations in drug sensitivity of organisms during a cell division cycle could produce such an effect; the results of experiments with cultures of synchronously dividing organisms have eliminated this possibility. Secondly, Ormerod (1951b) suggested that a slow penetration of dimidium bromide into organisms might explain the slow action of the drug. This explanation seems unlikely for the case of *S. oncopelti* since non-growing but actively metabolizing organisms (i.e. organisms incubated under the conditions described which do not permit multiplication or net synthesis of either protein or nucleic acid) can be exposed to both ethidium and dimidium bromide for long periods without any loss of viability. A third possibility is that the drugs penetrate into organisms rapidly but are not inhibitors of multiplication until they become bound on to, or incorporated into, a cellular component which only becomes available for this combination during growth. Such an explanation is compatible with some of the results obtained in the present work, but it does not explain the rapid binding of 14C-labelled drugs by non-growing organisms. The results described in the present paper can be explained by postulating two types of combination between drug and organisms: a rapid
combination with 'primary binding sites' which does not interfere with growth and cell division and which occurs in both non-growing and growing organisms, and then a slower combination with 'secondary binding sites' which become available to the drug during growth. It is this secondary uptake which results in a progressive decrease in the growth rate of organisms. The nature of these binding sites is not yet known, but there is some evidence to suggest that nucleic acid may be involved: the drugs can combine with, and are inactivated by, nucleic acid (Brownlee et al. 1950; Seaman & Woodbine, 1958); cytochemical studies (Ormerod, 1951b) suggest that the chromophilic granules which appear in the cytoplasm of drug-treated organisms contain ribonucleic acid, protein and bound drug, and the present work indicates that there is a close relationship between the combination of drug with 'secondary binding sites' and ribonucleic acid synthesis.

Inactivation of ribonucleic acid at the time of its synthesis might explain the observed progressive decrease in the growth rate of drug-treated organisms, since a correlation between the growth rate and ribonucleic acid content of cells has now been established for a number of microorganisms (Casperson & Brand, 1941; Jeener & Brachet, 1944; Caldwell, Mackor & Hinshelwood, 1950; Gale & Folkes, 1958). However this would not explain the rapid inhibition of deoxyribonucleic acid synthesis which occurs before the inhibition of either ribonucleic acid or protein synthesis, unless an active ribonucleic acid or ribonucleoprotein is in some way involved in deoxyribonucleic acid synthesis. Such a conclusion cannot be drawn from the experimental evidence available at the present time and a direct interaction between ethidium bromide and deoxyribonucleic acid cannot be excluded. It is hoped that further study of the mechanism of action of phenanthridine drugs may give some information about the interrelationships existing between deoxyribonucleic acid, ribonucleic acid and protein synthesis.

I wish to thank Dr D. H. Marrian of the Department of Radiotherapeutics, Cambridge, for making radioactivity measurements which involved the use of a windowless, gas-flow, counter.
