

**The Effect of Temperature on the Sensitivity of *Bacillus cereus* to Penicillin**

**By R. KNOX and P. COLLARD**

*Department of Bacteriology, Guy's Hospital Medical School, London*

**SUMMARY:** A strain of *Bacillus cereus* known to produce penicilllinase adaptively was tested for penicillin sensitivity at different temperatures. With small inocula, the organisms grew freely at 37°C in concentrations of penicillin up to a hundred times greater than those which completely suppressed their growth at 42°C. This difference in apparent sensitivity almost disappeared when the inoculum was very heavy or consisted of cells which had been allowed to adapt by previous growth in the presence of penicillin.

The penicillinase of *Bacillus cereus*, NRRL 569 was shown by Pollock (1950) to be formed adaptively. He also found that 'no significant amount of enzyme was formed at 18°C, and about four times as much at 35°C as at 80°C'. In earlier work on the adaptive formation of bacterial tetrathionase (Knox & Pollock, 1944), it had been found that the process of adaptation was much more sensitive to heat than was the fully formed enzyme (Pollock, 1945), while the known growth-promoting effect of tetrathionate in semi-anaerobic conditions (Knox, 1945) was suppressed at temperatures such as 42°C at which adaptive formation of the enzyme was also suppressed (Knox, 1950).

In view of these facts, it was decided to study the effect of temperature on the growth of a known penicillinase-producing organism in the presence of penicillin.

**METHODS**

The organism used was *B. cereus*, NRRL 569 obtained from Dr Pollock. Cultures were maintained by serial subculture at weekly intervals on slopes of nutrient agar kept at room temperature. From these, 6 or 18 hr. broth cultures were used to inoculate experimental tubes or flasks. In most experiments 6 in. x ½ in. tubes were incubated in water-baths having a range about the stated temperature of ± 0.5°C. In a few experiments 250 ml. conical flasks were used to obtain better aeration by increasing the surface/volume ratio. Growth after 18 hr. incubation was measured roughly by visible opacity (recorded as + or 0), or, where quantitative comparisons were wanted, on the density scale (at 400) of a Unicam spectrophotometer; rectangular cells 1 cm. in depth were used, with a sample of uninoculated medium as a 'blank'. It was found that with an 18 hr. culture in broth a density reading of 0.2 was given by 285 x 10⁶ cells/ml. (dry weight 0.27 mg./ml.).

**RESULTS**

*The effect of temperature on growth in nutrient broth*

In nutrient broth in the absence of penicillin it was found that the organisms grew well over the range 22–45°C but failed to grow at 48°C. At 45°C quantitative measurements of growth could not be made because of pellicle formation.
Table 1 shows the results of inoculating 0.02 ml. of an 18 hr. broth culture into 10 ml. of nutrient broth incubated for 18 hr. at different temperatures. It is clear that the organisms grew adequately up to temperatures as high as 42°, though, as would be expected, growth in flasks was much heavier than in tubes. In another experiment good growth was also obtained up to 42° in tubes of broth inoculated with 0.02 ml. of a 1/1000 dilution of an 18 hr. broth culture.

The effect of temperature and inoculum size on growth in penicillin broth

In broth containing 10 units of penicillin/ml. good growth was obtained up to 42° when a large inoculum was used, but only up to 37° when the inoculum was a thousand times smaller (Table 2). The effect of different inocula upon the penicillin sensitivity at 37 and 42° was then further investigated. 0.02 ml. of 1/1, 1/10, 1/100 and 1/1000 dilutions of a 6 hr. broth culture of B. cereus were inoculated into tubes of broth containing 0, 1, 10, 100 and 1000 units of penicillin/ml. (Table 3A). It is evident that inoculum size was much more critical at 42° than at 37°.

The effect of previous adaptation on growth of different inocula in penicillin broth at 37° and 42°

Pollock (1950) showed that maximal adaptive production of penicillinase demanded conditions of full aeration. In the experiment shown in Table 3, three sets of inocula were prepared from cultures of B. cereus grown in broth for 6 hr. at 37°—A in a 250 ml. conical flask, B in a 6 in. x ½ in. tube containing 1 unit of penicillin/ml. broth and C in a 250 ml. conical flask containing 1 unit
Penicillin sensitivity of B. cereus

of penicillin/ml. broth. Each inoculum was standardized to the same opacity and 0.02 ml. of different dilutions inoculated into tubes of broth as shown. After 18 hr. incubation the following results were obtained: (1) the level of penicillin in which the organism grew was in all cases a function of inoculum size; (2) at 37° there was no difference between the levels tolerated by equal inocula of the three types of cell; (3) at 42° the adapted cells were able to grow in from 10 to 100 times greater concentrations of penicillin than the unadapted cells; (4) with the smaller inocula the cells adapted in the flask grew in even higher concentrations than those adapted in the tube.

+=good growth; =faint growth; 0 =no growth. All tubes were examined after incubating for 18 hr. and then for a further 72 hr. Brackets indicate those tubes which showed a change, e.g. 0(+) =no growth at 18 hr., good growth after a further 72 hr.

It should be noted that when the tubes were incubated for a further 72 hr., growth was found to have occurred in many of the cultures which had previously shown no growth, though others showed no growth after still further incubation, even in the presence of added penicillinase (Glaxo Laboratories, Greenford).

DISCUSSION

It seems that the apparent tube sensitivity of an organism is the resultant of a number of factors of which inoculum size and temperature are perhaps the most obvious. The effect of inoculum size upon the apparent sensitivity of penicillinase-producing organisms has been known for some years and has been used by Luria (1946) as the basis of a test for differentiating such organisms from other penicillin-resistant strains. The possible effect of temperature has not been so widely appreciated.

The most reasonable explanation of our findings appears to be as follows: All cells of B. cereus 569 possess a basal quantity of penicillinase which can
hydrolyse penicillin at 37° and 42°. The adaptive production of penicillinase can
take place at 37° but not at 42°. Growth cannot take place at penicillin
concentrations above a certain level, approximately 1–2 units/ml. The fate of
cells inoculated into penicillin containing media depends partly on the initial
penicillin level and partly on the available penicillinase, which is itself
determined by the size of the inoculum and the possibility of adaptation.
There will therefore be a longer or shorter lag period during which penicillin is
being destroyed but no growth is possible until this falls below the critical level.
If sufficient cells survive this period, then growth will occur on prolonged
incubation; on the other hand, the cells may suffer irreversible damage and
die.

The experiments here described and the results obtained previously with
tetrathionase provide two clear examples of the importance of adaptive
mechanisms in bacterial growth. Both tetrathionase and penicillinase can be
formed by a process of enzymic adaptation in conditions which exclude natural
selection. Both adaptive processes are more sensitive to heat than the process
of growth in the organisms investigated. In both cases it can be shown that if
conditions are suitably chosen adaptation is a necessary condition for growth,
and when penicillin is the substrate, it may even be a necessary condition for
survival, since sensitive cells will be destroyed by penicillin if they cannot
produce enough penicillinase to neutralize it first.

Adaptive mechanisms of this kind may be of vital importance for bacterial
growth not only in the laboratory, but also in the animal body. For example,
one way in which pyrexia could benefit the host is by suppressing adaptive
mechanisms essential for survival and multiplication of the parasite. If this
were so, reduction of body temperature by the use of antipyretic drugs could
even swing the balance in favour of the parasite. Pasteur and his colleagues
observed in 1878 (Pasteur, Joubert & Chamberland, 1878) that fowls naturally
immune to anthrax could be infected if the body temperature were artificially
reduced. Pasteur's conclusion that the high body temperature (42°) of the fowl
suppressed the growth of B. anthracis was criticized when it was found that the
organism grew well in the laboratory at 42–43°. But this criticism would lose
its force if the virulence of B. anthracis were found to depend on a thermolabile
adaptive mechanism of the kind we have here described.

Artificially induced pyrexia, local or general, has been used in the treatment
of a number of infections and some benefit might be expected from combining
it with the use of antibiotics. This could occur in two ways: (1) as suggested
by Marks (1951), in a recent paper on the effect of temperature on the sensitivity
of tubercle bacilli to antibacterial agents, by suppressing the growth of all
organisms except a few rare variants resistant to both the antibiotic and the
higher temperature; (2) by the suppression of adaptive mechanisms in the
parasite as, for example, in mixed infections complicated by penicillinase-
producing organisms.

We should like to thank Dr M. R. Pollock for the strain of B. cereus and
Mr R. Woodroffe for technical assistance.
