(Accepted for publication 13 October 1971)

SUMMARY

Procedures for mutagenesis and conditions for selection by penicillin enrichment in the blue-green alga *Anacystis nidulans* have been developed. The characterization of 19 mutant strains involving single or serially induced multiple markers was achieved. In addition to drug-resistant and morphological mutants auxotrophic strains requiring phenylalanine, methionine, biotin or acetate together with strains deficient in sulphate and nitrate reduction have been isolated.

INTRODUCTION

Previous attempts to isolate mutants of blue-green algae have had only limited success, and in particular auxotrophic mutants have proved difficult to obtain. Although several species of blue-green algae are significantly more resistant to γ-radiation than are bacteria (Kraus, 1966) other mutagens, ultraviolet light (u.v.) and N-methyl-N'-nitro-N-nitroso-guanidine (NTG) are comparably lethal to species from both groups of procaryotic organisms. Mutations affecting u.v. and drug resistance have proved the most readily recovered, and several such mutants of the unicellular blue-green alga *Anacystis nidulans* have been reported although not always as clonally pure strains (Kumar, 1962, 1963, 1965; Singh, Singh & Sinha, 1966; Pikalek, 1967; Bazin, 1968; Asato & Folsome, 1969; Shestakov & Khyen, 1970). Morphological and pigment alterations have been shown in mutants of *Anabaena cycadeae* (Singh & Singh, 1964a), *Anabaena doliolum* (Singh & Singh, 1964b), *Nostoc linchiae* (Singh & Tiwari, 1969), *Plectonema boryanum* (Padan & Shilo, 1969), *Agmenellum quadruplicatum* (Ingram & Van Baalen, 1970) as well as in the more studied *Anacystis nidulans* (Van Baalen, 1965; Kunisawa & Cohen-Bazire, 1970). The best characterized auxotrophic mutants of blue-green algae are the nitrate-reductase and nitrite-reductase mutants of *Agmenellum quadruplicatum* described by Stevens & Van Baalen (1970); strains of *Anacystis nidulans* lacking nitrate reductase have also been isolated (Van Baalen, 1965). The requirement for a non-specific reduced carbon source has been reported in a mutant of *Phormidium mucicola* (Srivastava, 1969) and in *Anacystis doliolum* (Singh & Singh, 1964b). This communication describes the development of conditions for mutation and penicillin enrichment which have led to the isolation of 19 mutant strains of *Anacystis nidulans* which carry single or multiple mutations affecting morphological, drug resistance and nutritional characters.

METHODS

Organism. The parent strain for all the mutants isolated was *Anacystis nidulans*, no. 625 of the Culture Collection of Algae at Indiana University, Department of Botany, Bloomington, Indiana, U.S.A.
Culture media and conditions. *Anacystis nidulans* was grown in liquid culture and on agar plates as previously described (Herdman, Faulkner & Carr, 1970).

Supplemented media. For the isolation and growth of mutants Allen's media was supplemented with the necessary growth factors at the concentrations listed below: inorganic salts, NH₄Cl, 3 mM; Na₂S₂O₃ and NaNO₃, 1 mM; carbon sources, Na acetate, 2 mM; malic acid and formic acid, 0.5 mM; shikimate, 0.1 mM; vitamins, biotin, thiamine, B₁₂, nicotinic acid, 5 µM; nucleotides, thymine, thymidine, uracil, 0.5 mM; amino acids, arginine, aspartate, cysteine, glutamate, isoleucine, leucine, methionine, proline, serine, threonine, valine, 1.0 mM; alanine, phenylalanine, 0.1 mM. Tyrosine at 2 mM was used for development of resistant strains; antibiotics, streptomycin 25 µg/µl; polymixin-B 100 µg/ml.

Incorporation of [¹⁴C]-labelled materials. [²⁻¹⁴C]acetate (25 µCi, 55 µCi/mmoll) was added to an exponentially growing culture (100 ml) of the acetate requiring mutant A163 growing in acetate supplemented medium and samples (5 ml) were removed at intervals up to 8 h. Organisms were immediately collected on a membrane filter and washed (8 ×) with small volumes of medium. After drying, the filters were glued to an aluminium planchette and isotope incorporation estimated in a Nuclear Chicago low background gas-flow counter at an efficiency of 30 % and to an accuracy of ± 3 %. The same procedure was used for measurement of [methyl-¹⁴]methionine incorporation into nitrate-reductase deficient, methionine-requiring mutant A2112.

Optimal conditions for mutagenesis. Optimal exposure times to ultraviolet light (u.v.) and N-methyl-N'-nitro-N-nitrosoguanidine (NTG) were found by exposing two mutants, A111 (deficient in nitrate reductase) and A121 (deficient in sulphate reduction), to the mutagens and observing the dose which gave maximum reversion to wild-type.

Ultraviolet light. Cultures of the mutants were concentrated to 3 × 10⁹ cells/ml by centrifugation and resuspended in fresh growth medium. The suspensions were irradiated at 254 nm under a Camag Universal u.v. lamp (Camlab, Cambridge). Samples (1 ml) were removed at intervals and plated directly on minimal medium to score revertants, and also diluted and plated on supplemented medium to estimate viable count.

Nitrosoguanidine. A 4 ml suspension containing 3 × 10⁹ cells/ml was added to 16 ml growth medium containing NTG (Aldrich Chemical Co. Inc., Milwaukee, Wisconsin, U.S.A.) to a final concentration of 25 µg/ml at pH 8.0. Samples (1 ml) were removed at intervals, filtered through a sterile Millipore filter, washed, resuspended in sterile-distilled water, and plated as described above.

Optimal conditions for penicillin enrichment. The penicillin enrichment technique was applied to the isolation of mutants of *Anacystis nidulans*. A mixture of wild-type and strain A111 or wild-type and strain A121 cells in the ratio wild-type: mutant (3:1) was grown from 5 × 10⁷ to 6 × 10⁸ cells/ml in medium containing NH₄Cl or Na₂S₂O₃ respectively. The culture was centrifuged, washed and resuspended in minimal medium at 1 × 10⁷ cells/ml and then allowed to grow for 4 h to permit cessation of growth of mutant cells. Under these conditions wild-type cells divided twice in this period, and the final cell count was 3 × 10⁷ cells/ml. After 4 h growth penicillin (60 µg/ml) was added to the culture. Samples (1 ml) were removed at intervals, filtered, washed to remove traces of penicillin, resuspended in sterile-distilled water and plated on supplemented medium to score the total viable counts. Colonies were then replica plated on to minimal and supplemented medium to score the numbers of wild-type and mutant cells in the sample.

Isolation of auxotrophic mutants. A 2 ml sample of an exponentially growing culture (5 × 10⁸ cells/ml) was added to 8 ml of growth medium containing NTG at a final concentration of 25 µg/ml, and incubated for 60 min. The sample was filtered through a Millipore
Mutants of Anacystis nidulans

filter, washed, and resuspended in 100 ml of supplemented medium. This culture was grown to $5 \times 10^8$ cells/ml and a 10 ml sample was filtered, resuspended in minimal medium (100 ml) and exposed to 60 $\mu$g/ml penicillin for 2 to 2½ h as described above. Penicillin was removed by filtration and washing with 30 ml water for a 10 ml sample and the cells resuspended in 100 ml supplemented medium and allowed to grow to a density of $3 \times 10^9$ to $8 \times 10^8$ cells/ml. The culture was diluted and plated on supplemented agar plates as previously described to give 200 to 350 colonies/plate. The colonies were replica plated on minimal and supplemented agar using filter paper. Colonies which were identified as mutants were picked off, streaked on to supplemented agar, and their growth requirements identified on agar and in liquid medium. This procedure permitted 10,000 to 20,000 colonies to be screened in each experiment.

Isolation of resistance mutants. Cultures were exposed to NTG as described above, and subsequently grown to approximately $8 \times 10^8$ cells/ml in the absence of the compound to which resistance was being sought. The culture was then plated directly on to agar containing the compound, and resistant colonies isolated.

Nomenclature of mutants. The proposals of Demerec, Adelberg, Clark & Hartman (1968) have been followed.

RESULTS

Penicillin enrichment. Wild-type and mutant (1111 and 1121) cells exhibited differential survival during exposure to penicillin in minimal medium (Fig. 1). The viable count of strains 1111 and 1121 decreased to 60 and 80 % respectively of the initial values after 2 h exposure to penicillin. The viable count of wild-type cells decreased more rapidly, and after 2 h exposure only 0·5 % of wild-type cells were viable. The viable count of wild-type cells decreased further to 0·15 % after 3 h exposure to penicillin; after this time no further reduction in viability was observed.

Thus exposure to penicillin equivalent to one doubling time (2 h) killed 99·5 % of wild-type cells but only 20 to 40 % of mutant cells. This differential survival represents a 100-fold enrichment of mutant cells.

Ultraviolet mutagenesis. The survival of strains 1121 (Fig. 2) and 1111 (Fig. 3) to U.V. differed, in that the culture of strain 1111 appeared to contain a proportion of u.v.-resistant cells which were not observed in cultures of strain 1121. Maximum reversion frequencies, however, occurred at similar doses in both mutants, i.e. at 3 % survival of 1121 and 1 % survival of 1111. The number of mutants increased rapidly with increasing exposure to u.v. up to this point, and then decreased at a rate parallel to the inactivation of the culture. The maximum reversion frequencies were $2.3 \times 10^{-5}$ for 1121 and $1.8 \times 10^{-5}$ for 1111.

NTG mutagenesis. The response of strain 1111 to NTG (25 $\mu$g/ml) is shown in Fig. 4: the viable count decreased with increasing exposure. The number of mutants increased rapidly with time, until a maximum was attained after 60 min exposure. At this time, 0·4 % of the population were viable and 3·52 % of these survivors were revertants to wild-type. Of these revertants 3·41 % (0·12 % of the total survivors) had acquired filamentous form (Fil).

Characterization of mutants. The mutants isolated by the methods described above are shown in Table 1. Nitrate reductase-deficient mutants were isolated at high frequencies (approximately $1 \times 10^{-3}$) after penicillin treatment, but were found at lower frequency ($1 \times 10^{-4}$) without enrichment. Acetate-requiring mutants were observed with frequencies of $1 \times 10^{-5}$ in the absence of enrichment and $5 \times 10^{-3}$ following enrichment. Biotin, phenylalanine and methionine-requiring strains were recovered with frequencies of approximately

5 × 10⁻⁴ following enrichment, and were not isolated in experiments where enrichment was not applied. NTG-induced mutants resistant to streptomycin, polymixin-B or tyrosine arose at low frequencies in the range 10⁻⁵ to 10⁻⁷. Filamentous mutants were found at high frequencies (10⁻² to 10⁻³) even though penicillin enrichment could not be applied to mutants of this type.

The growth rates of the mutants isolated were similar (± 10 %) to that observed in wild-type Anacystis nidulans, i.e. 0.11 doublings/h. As far as they were tested the auxotrophic strains described had a specific growth requirement; for example 1163 (Ace) did not grow on malate, citrate, fumarate, glutamate, glycine, glucose or glyoxylic acid, and the requirement for methionine of strain 2112 (Nit Met) could not be replaced by Na₂S₂O₃, cysteine, homocysteine, choline, formate, acetate, pyruvate or vitamin B₁₂. For auxotrophic mutants the accumulation of ¹⁴C-labelled nutrient was followed during growth. Under the conditions employed the acetate requiring strain 1163 incorporated [2-¹⁴C]acetate at a linear rate twice that of the wild-type; after 7 h growth incorporation ceased. The assimilation of [methyl-¹⁴C]methionine by the methionine requiring strain 2112 was faster than the wild-type, but after 2 h entry into both cultures continued at a reduced, similar, rate up to a period of at least 8 h.
DISCUSSION

The results demonstrate that u.v. is a relatively inefficient mutagen for *Anacystis nidulans*, giving a maximum crude mutation frequency of $2.3 \times 10^{-6}$ for the two genes tested. NTG, however, was 1000-fold more effective in mutagenesis, giving a maximum mutation frequency of $3.4 \times 10^{-6}$ and producing double mutants with a frequency of up to $1.2 \times 10^{-3}$. The maximum mutation frequency resulting from exposure to NTG occurred at a dose where 0.4% of the culture was viable. This is much less than in bacteria, in which maximum mutation frequencies occur at doses which permit 50% survival of the treated culture (see Adelberg, Mandel & Chen, 1965).

All the mutants reported in this paper were isolated after exposure to NTG at pH 8. Preliminary experiments showed no difference in the mutagenic action of NTG in growth medium (pH 8) or in phosphate buffer at pH 5. At pH 8, diazomethane, a decomposition

Mutants of Anacystis nidulans

product of NTG, is thought to be the principle agent involved in mutagenesis (Cerda-Olmedo & Hanawalt, 1968). The penicillin enrichment technique proved valuable in the isolation of auxotrophic mutants, since the frequency of isolation of such mutants was increased by approximately 20 to 100-fold by this technique. Thus Nit and Ace mutant strains were isolated at frequencies of $1 \times 10^{-2}$ and $5 \times 10^{-5}$ respectively following enrichment of the cultures, but at the lower frequencies of $1 \times 10^{-4}$ and $1 \times 10^{-8}$ respectively in the absence of enrichment. The degree of enrichment illustrated by these values was in general agreement with the results obtained during the development of the technique. The nitrate reductase deficient mutants appear similar to that described by Van Baalen (1965) and the filamentous mutants (Fil) possessed morphological changes similar to those described by Kunisawa & Cohen-Bazire (1970), in that 1101 was a long single filament (analogous to class II of Kunisawa & Cohen-Bazire) and 1102 possessed cells of variable length up to tenfold that of the wild-type (Kunisawa & Cohen-Bazire, class I).

The relative difficulty in isolation of auxotrophic and other mutant phenotypes of blue-green algae has been noted by other workers but it is evident that Anacystis nidulans is sensitive to NTG to an extent comparable to other procaryotes. Although some phenotypes (e.g. Nit, Fil) were isolated at relatively high frequencies, others were not found after extensive screening. The reason for the isolation of only a narrow spectrum of mutants of A. nidulans is not known, but may be related to the autotrophic metabolism of the organism since the same difficulties are encountered in the isolation of mutants of autotrophic, eucaryotic algae (Li, Redei & Gowans, 1967).

The use of the techniques described in this paper has led to the isolation of auxotrophic mutants which have not previously been reported in blue-green algae, namely those requiring cysteine (thiosulphate), biotin, methionine, phenylalanine and acetate, and the tyrosine-resistant mutant.

The authors are indebted to Dr B. M. Faulkner for valuable advice and M. H. acknowledges financial support from the Science Research Council.
