(Accepted for publication 17 November 1971)

SUMMARY

A study of the ultrastructural characteristics, the physiological properties and an analysis of hydrolysates of phenol-treated cell walls of *Corynebacterium rubrum* were made. While the arabinogalactan-peptidoglycan complex found in the cell-wall hydrolysates was that common to the genera *Corynebacterium*, *Mycobacterium* and *Nocardia*, the ultrastructural patterns found, the physiological reactions observed, the sensitivity to nocardiphages but not to corynebacteriophages or mycobacterial phages, and the (previously reported) presence of nocardomycolic acids, combined with the absence of corynemicolic acids and mycolic acids, indicate that this species belongs in the genus *Nocardia* rather than in the genus *Corynebacterium*.

It is proposed, therefore, that *Corynebacterium rubrum* be renamed *Nocardia corynebacteriodes* nomen novum.

INTRODUCTION

*Corynebacterium rubrum* was described by Crowle (1962). Gordon (1966) proposed the reclassification of this species as a member of the 'rhodochrous' group. The ultrastructure of wild-types of the genera *Mycobacterium*, *Nocardia* and *Corynebacterium* has been investigated and revealed structural differences in their cell walls (Imaeda & Ogura, 1963; Kawate & Inoue, 1965; Farshtchi & McClung, 1967; Lickfeld, 1967; Montez & Black, 1967; Imaeda, Kanetsuna & Galindo, 1968; Beaman & Shankel, 1969; Hard, 1969).

The phenol-treated cell wall is composed of a mycolic acid–arabinogalactan-peptidoglycan complex, the common structural component of mycobacterial cell walls (Kanetsuna, 1968), suggesting that this complex may be of taxonomic significance.

The purpose of this study was to examine the physiological and ultrastructural characteristics of *Corynebacterium rubrum* in relation to its classification. Chemical and morphological analyses were made of cell wall components obtained by various chemical and enzymatic treatments.

METHODS

*Corynebacterium rubrum* ATCC14898 was maintained on tryptose-phosphate broth (TPB) Difco, supplemented with 5 % glycerol and 0.04 % Tween 80, for ultrastructural and chemical studies.

For physiological studies, nutrient broth, brain heart infusion (BHI) broth, glucose yeast extract medium (Waksman, 1950), Kirchener’s medium (Crowle, 1962), Farshtchi’s medium (Farshtchi & McClung, 1967), Middlebrook 7H9 glucose and Lowenstein–Jensen medium
(Difco) were used. Sugar tests were carried out according to the methods recommended by Barksdale, Li, Cummins & Harris (1957), Gordon & Mihm (1957, 1959); Edwards & Ewing, (1962) and Gordon (1966). Carbohydrates (1%, w/v) were sterilized by filtration and added aseptically to the medium. Glucose was used at 1.5% final concentration.

Organic acids as carbon source used at 0.2% final concentration (Gordon & Mihm, 1957). Tests for indole production, methyl-red, Voges-Proskauer, H2S production, growth in KCN, nitrate reduction and decarboxylation of amino acids were made by the methods recommended by Edwards & Ewing (1962).

Cultural condition for ultrastructural and chemical studies. Cultures in liquid media were aerated on an orbital shaker at 37° for morphological studies. For cell-wall preparations, organisms grown in liquid media for 1 week at 37° without shaking were killed with formaldehyde (0.5% final concentration). After several hours the bacteria were sedimented at 10000g for 15 min. They were disrupted in a mortar with dry ice, followed by sonication at 20 kHz for 1 h with a Branson sonifier in an ice bath.

The suspension was centrifuged at 15000g for 20 min to discard unbroken cells and the supernatant fluid was recentrifuged at 10000g for 30 min.

Sediments were treated with 0.5% trypsin (Sigma) in 0.1 M-phosphate buffer pH 7.6 at 37° for 6 h to remove the remaining cytoplasmic components. Insoluble material was collected by centrifuging at 10000g for 20 min and washed in distilled water several times. The cell walls thus prepared were examined with a Baush & Lomb Spectronic 600 spectrophotometer at wavelengths ranging from 230 to 300 nm to check for the presence of nucleic acids as an indication of cytoplasmic contaminants. The preparation not showing any specific absorbance at 260 nm was used as the cell-wall fraction.

Treatment of the cell walls with 90% (w/v) phenol was performed (Imaeda et al., 1968; Kanetsuna, 1968) to obtain the lipopolysaccharide peptidoglycan complex; 45% (w/v) phenol was also used to eliminate free protein and lipopolysaccharide from the phenol-insoluble lipopolysaccharide–peptidoglycan complex. Cell walls were also treated with 0.1% pancreatin in 0.1 M-phosphate buffer at pH 7.6 for 6 h, 5% TCA at 4° for 72 h or 0.4% sodium dodecyl sulphate (SDS) (Sigma).

Chemical analysis of phenol-treated cell-wall fractions. For the determination of sugars, lipids, amino sugars and amino acids, samples of cell walls were examined as previously described (Kanetsuna, 1968). Quantitative determination of amino acids was carried out with a JEOL amino acid analyser JLC-3BC.

Electron microscopy. Whole organisms and cell walls, either without treatment or after treatment with different neutral solvents, were positively or negatively stained with 2% sodium silicotungstate at pH 7.5.

To obtain ultrathin sections the organisms at various stages of growth were centrifuged, and fixed by the methods of Ryter & Kellenberger (1958). Fixation with 4% formaldehyde in 0.15 M-tris-HCl buffer pH 7.4 containing 1% NaCl and 0.2% CaCl2 by a modification of Stoeckenius method (Stoeckenius & Rowen, 1967; Imaeda et al., 1969) was also employed, followed by treatment with 1% osmium tetroxide or 1% potassium permanganate. After dehydration with acetone, cells were embedded in Araldite.

* This activity is inhibited by warming the cells at 68° in water bath for 20 min.
Fig. 2. Electron micrograph showing negatively stained (silicotungstate) *Corynebacterium rubrum* after 20 min agitation in physiological saline. Note how the 'fibrillar-like' substance that covers the surface of the cell has been partially removed (arrows) by this treatment.

The ultrathin sections were cut with a MT-2 Porter-Blum ultramicrotome and double stained with uranyl acetate and lead citrate. The electron microscopes used were a Hitachi HU-11B, HS-6 and JEM 7-A.
RESULTS

Physiology and gross morphology of *Corynebacterium rubrum*

*Corynebacterium rubrum* is aerobic. It grows in tryptose phosphate, nutrient broth, brain–heart infusion broth (Difco), glucose–yeast extract medium and Lowenstein–Jensen media, at $37^\circ$, in chemically defined media such as Kirchener's medium and Middlebrook 7H9 glucose (Difco). In stationary liquid media growth starts with the production of a fine...
dark-orange sediment which after about 35 h at 37° forms an orange-red film on the surface of the media. Colour becomes more intense in the glucose yeast extract media. In chemically defined media the orange-red film appears more rapidly and has a dry appearance. On solid media orange-red pigmented colonies with a granular central region are surrounded by a smooth and shiny peripheral zone.

By phase-contrast bacterial cells were seen in pairs, V forms, clumps and palisade arrangements (Fig. 1). It is Gram-positive, not acid-fast, and has metachromatic granules and lipophilic granules in its cytoplasm when stained by Albert’s method or with oil red O. Results of the physiological tests applied to the Corynebacterium rubrum are presented in Table 1.

Corynebacterium rubrum is sensitive to 10 i.u. bacitracin/ml, and 2 i.u. penicillin/ml in quantitative antibiotic sensitivity test and sensitive to 2 mg lincomycin, 10 μg oxytetracycline, 10 μg chloramphenicol, 5 mg neomycin, 2 mg erythromycin, 1 μg sulphathiazole, 25 μg ampicillin, 2 μg dehydrostreptomycin, 30 μg novobiocin and 25 μg cephalotin in qualitative sensitivity test with antibiotic discs (Difco).

Fig. 4. (a) Electron micrographs of negatively stained (silicotungstate) Corynebacterium rubrum cells. (a) Treatment with 0.1 % pancreatin (6 h at 37°) partially removed the fibrillar-like substance from the surface, disclosing an underlying network of fibrils 8 to 10 nm in diam. (arrows). (b) After phenol extraction, both the outermost fibrillar-like substance and the underlying network of fibrils observed in (a) were removed. An innermost network of fibrils (arrows) with a mean diam. of about 4 nm is now detected.
Fig. 5. Electron micrograph of a longitudinal section of a Corynebacterium rubrum cell after double fixation with formaldehyde and \text{OsO}_4. The fibril-like structure (arrows) is observed adherent to the outermost surface of the cell. Note the vesicular structure of the mesosome ($m$) in relation to the septum ($s$). Remains of mesosome membranes are also detected ($mm$).

**Ultrastructure**

Negatively stained cells of *Corynebacterium rubrum* are covered with a fibril-like substance (Fig. 2) which can be partially removed by sonication and neutral solvents. Treatment with neutral solvents transforms fibrils into a crystal-like substance *in situ* or after they are...
Fig. 6. A positively stained (silicotungstate) *Corynebacterium rubrum* cell, during active division. The formation of the septum is completed and the mesosomes with a tubular appearance are seen at both sides of the septum. Structures similar to those described as polyphosphate granules are also detected within the cells.

removed from the cell surface (Fig. 3). The shape of the crystal-like material is not altered by treatment with 0.5% trypsin, pancreatin or pepsin. This outermost fibrillar layer, which may correspond to the outermost diffuse dense layer seen in ultrathin sections (Fig. 5) is a unique surface substance of this species and has never been observed by us on the surface of any mycobacterium, nocardia or corynebacterium.

When the organisms were agitated for 20 min with physiological saline, the outermost fibrillar layer was partially removed disclosing an underlying layer. Treatment with 0.1% pancreatin at 37°, or 5% TCA at 4° also removed the outermost layer. The underlying layer was composed of a network of fibrils of 8 to 10 nm diam. (Fig. 4a). SDS (0.4%) and phenol removed completely the innermost fibrillar network layer containing fibrils of about 4 nm diam. (Fig. 4b).

In ultrathin sections the cell wall is composed of an outermost diffuse layer and a middle moderately dense layer 10 nm thick which adheres to the plasma membrane. The total thickness of the cell wall is about 18 to 20 nm. The plasma membrane is often seen to be continuous with the mesosome.

In the cytoplasm, granules possibly representing polyphosphate are observed along with other cytoplasmic structures such as ribosomes and a nuclear region (Fig. 5, 6). The mesosome in positively stained cells is revealed as a tubular structure which appears to be lamellar or vesicular in ultrathin sections (Fig. 6); occasionally the mesosome shows contact with the nuclear area.

Table 2 shows the chemical composition of the phenol-treated cell walls of Corynebacterium rubrum. This fraction has ω, ε-diaminopimelic acid, glutamic acid and alanine as the principal amino acids and glucosamine and muramic acid as the principal amino sugars.

The molar ratio of diaminopimelic acid, glutamic acid, alanine, muramic acid and glucosamine is 1111:90:90:90:90:90:90. The sugars contained in this fraction are arabinose and galactose. These components may be considered to form an arabinogalactan–peptidoglycan complex, as reported in Mycobacterium and Nocardia (Cummins & Harris, 1958; Kanetsuna, 1968; Cunto, Kanetsuna & Imaeda, 1969). There are not mycolic acids in this fraction.

**DISCUSSION**

On physiological characteristics, Corynebacterium rubrum has been included within the ‘rhodochrous’ group. The physiological assays that were carried out during this investigation lead us also to consider that this species does not belong to the genus Corynebacterium but rather to be more closely related to Mycobacterium or Nocardia. However, the ultrastructure of C. rubrum is different from that observed in wild-type of strains of Corynebacterium.

For example, the presence of an outermost dense cell-wall layer in Corynebacterium minutissimum, Corynebacterium diphtheriae and Corynebacterium ovis (Lickfeld, 1967; Montez & Black, 1967; Hard, 1969) and the multiseptum formation sometimes observed in C. diphtheriae (Lickfeld, 1967) make these species very different from Corynebacterium rubrum. On the other hand, several mutants of mycobacteria which contain red pigment show very similar ultrastructural characteristics to those of C. rubrum (T. Imaeda, personal communication).

Many human and animal pathogenic corynebacteria and many mycobacteria and nocardia cell walls are characterized by arabinose, galactose and ω, ε-diaminopimelic acid (Cummins & Harris, 1958). The presence of this polymer in the Corynebacterium rubrum cell wall is not conclusive evidence that this species belongs to the genera Corynebacterium, Mycobacterium or Nocardia, but the isolation of nocardomycolic components from cell-wall analyses of C. rubrum (M. A. Lanelle, B. L. Beaman and W. L. Barksdale, personal communication) showed it to have low-molecular-weight nocardomycolic acids, suggesting that its taxonomic position was closer to Nocardia rubra than to Nocardia asteroides or Nocardia brasiliensis. Lechevalier, Horan & Lechevalier (1971) also reported the presence of nocardomycolic acid in C. rubrum and suggested that C. rubrum was lysed only by nocardiophages, but not by mycobacterial phages or by corynebacteriophages (Arden, 1970).

Based on the comparisons of ultrastructure, physiological characteristics, cell-wall composition and phage sensitivity it is concluded that Corynebacterium rubrum should be included in the genus Nocardia. It is proposed that this species be named Nocardia
corynebacteroides. The change in specific epithet is needed because the combination Nocardia rubra is pre-empted by Nocardia rubra (Kruse) Chalmers & Christopherson, which combination, according to Buchanan, Holt & Lessel (1966), is validly published and legitimate.

This research was partially supported by Consejo de Desarrollo Científico y Humanístico de la Universidad de Los Andes, Mérida, Venezuela, and was done in partial fulfilment of the requirements for the doctoral degree in the University of São Paulo, Brazil, by J. A. Serrano.

We wish to thank Miss Cecilia Maldonado and Mr Ramón Sulbarán for their valuable help in the elaboration of this work, and to Dr L. Barksdale and S. B. Arden for their suggestions, criticism and comments on the manuscript.
