(Received 4 December 1972)

SUMMARY

Two complementary frameshift mutations in the trpA gene of Escherichia coli have been isolated following recombination of the pseudowild double mutant with the wild-type strain. One of these mutations recombines with a third, distal frameshift mutation to give a slow-growing Trp+ strain. Consideration of the relevant RNA codon sequences suggests that the slow-growing recombinant should contain a unique tryptophan codon in the altered reading phase between the frameshift mutations. This prediction has been verified by analysis of the purified tryptophan synthetase A protein from the double mutant. The preferential synthesis of A protein normally associated with prolonged tryptophan starvation is eliminated in the strain which has a tryptophan residue in its A protein.

INTRODUCTION

The biosynthetic tryptophan (trp) operon of Escherichia coli contains five structural genes, trpE, D, C, B and A, which code for the five polypeptide chains involved in the conversion of the aromatic precursor chorismic acid to tryptophan (Yanofsky & Lennox, 1959; Creighton & Yanofsky, 1969). Expression of the operon is controlled by the protein product of an unlinked regulatory gene, trpR (Cohen & Jacob, 1959; Morse & Yanofsky, 1969; Zubay, Morse, Schrenk & Miller, 1972). An operator locus has been identified by the isolation of cis-acting constitutive mutants mapping at the E gene end of the operon (Hiraga, 1969). The five structural genes are transcribed into a single messenger RNA molecule, which is sequentially synthesized and translated from the operator-proximal E gene towards the distal A gene (Imamoto, Morikawa & Sato, 1965; Imamoto & Yanofsky, 1967).

When the trp operon is derepressed during normal growth the enzymes are produced in equimolar quantities (Ito, Cox & Yanofsky, 1969). This situation does not hold, however, when a tryptophan auxotroph is subjected to prolonged tryptophan starvation (Somerville & Yanofsky, 1964). The tryptophan synthetase α subunit, coded by the trpA gene, continues to be synthesized for some 30 h of starvation, whereas the other products of the operon are no longer produced after a few hours. Somerville & Yanofsky (1964) have suggested that this preferential synthesis of the α subunit is due to independent translation of the messenger RNA corresponding to the trpA gene, made possible by the absence of tryptophan from the α subunit (Henning, Helinski, Chao & Yanofsky, 1962). This hypothesis could be directly tested if there were available an α subunit variant which contained a tryptophan codon. This paper describes the isolation of such a variant, and shows that the altered A gene is no longer preferentially expressed during tryptophan starvation.
METHODS

Bacteria and phage. The various \textit{trp} mutants used in this study were crossed into the \textit{w3110} strain of \textit{Escherichia coli} by transduction with \textit{P1kc}, using a \textit{w3110 (tonB, \textit{trpE-A})} deletion as recipient, and selecting for growth on plates supplemented with indole (10 \textmu g/ml). Strains \textit{trpA46^wPR3} and \textit{trpA46^wPR3FR7} were generously provided by Dr H. Berger: other bacterial strains and the generalized transducing phage \textit{P1kc} were from the collection of Dr C. Yanofsky.

Media. The minimal medium of Spizizen (1958) was used with glucose (0.2\%, w/v) as carbon source. Where possible this was supplemented with 0.05\% (w/v) Difco Bacto acid hydrolysed casein. Amino acids were added as required at 20 \textmu g/ml. The rich medium was \textit{L-broth} (Lennox, 1955) containing (g/l): Difco Bacto Tryptone, 10; Difco Bacto Yeast Extract, 5; NaCl, 5; glucose, 1, adjusted to pH 7.2. Media for plates were solidified with 1.5\% (w/v) agar.

Transduction. \textit{P1kc} lysates were prepared by the confluent lysis technique (Swanstrom & Adams, 1951) and were used for transduction as described by Yanofsky & Lennox (1959).

Recombination distances between \textit{trpA} mutants were obtained as described by Yanofsky \textit{et al.} (1964). When the recipient was \textit{cysB, trp}, the ratio of \textit{cys^+trp^+} to \textit{cys^+} transductants was multiplied by 2 to correct for the 50\% \textit{cysB-trp} linkage (Yanofsky & Lennox, 1959). When a \textit{hiscysBtrp} recipient was used the ratio of \textit{cysB^+trp^+} to \textit{his^+} transduction was scored. When \textit{cys^+} and \textit{trp^+} are selected together, the 50\% \textit{cys-trp} linkage exactly compensates for the relatively inefficient transduction of the \textit{his} region compared with that of the \textit{cys-trp} region (Yanofsky & Lennox, 1959). In all crosses the \textit{cys^+trp^+} transductants were selected on minimal plates supplemented with 0.1 \textmu g/ml 5-methyl-\textit{D}-tryptophan, which suppresses the growth of leaky mutants without affecting the growth of wild-type recombinants or the frequency of recombination (Yanofsky \textit{et al.} 1964).

Penicillin enrichment for \textit{trp} recombinants. The procedure was based on that described by Allen & Yanofsky (1963). After exposure of the \textit{cysBtrp^+} recipient to transducing phage, organisms were harvested, washed in 0.1 M-sodium citrate buffer, pH 7.0, resuspended in minimal medium containing 0.2\% (w/v) glucose and 20 \textmu g/ml L-tryptophan, and grown overnight at 37 °C. The \textit{cys^+} transductants so selected were diluted 50-fold into fresh minimal medium containing glucose (0.2\%, w/v) and tryptophan (20 \textmu g/ml) and grown to about \(2 \times 10^8\) organisms/ml. Organisms were harvested and washed twice with minimal medium, resuspended at \(10^8\) organisms/ml in minimal medium + glucose (0.2\% w/v) and grown for a further 3 h at 37 °C. Benzylpenicillin (1000 u/ml) was then added and incubation was continued for a further 2 h before the organisms were washed twice in minimal medium and resuspended in the original volume of L-broth to grow to saturation. Approximately 200 organisms/plate were spread on to glucose-minimal agar plates supplemented with L-tryptophan (20 \textmu g/ml). Plates were incubated at 37 °C for 48 h before replication to unsupplemented glucose-minimal agar plates to screen for \textit{trp} colonies.

Preparation of extracts. Bacteria were harvested by centrifugation at 0 °C, washed with one-half the original volume of cold 0.1 M-tris-HCl, pH 7.8, and resuspended in 1/50 volume of the same buffer. Organisms were disrupted with a M.S.E. sonifier, and the debris was removed by centrifugation at 38000 \textit{g} for 15 min.

Enzyme assays. The A and B subunits of tryptophan synthetase were assayed by indole-utilization as described by Smith & Yanofsky (1962). A crude extract prepared from the \textit{A} gene nonsense mutant \textit{trpA96} was used as the source of the B protein. Specific activities...
are expressed as units of enzyme activity/mg of protein. Protein was determined by the procedure of Lowry, Rosebrough, Farr & Randall (1951).

Purification of tryptophan synthetase A proteins. Wild-type and mutant tryptophan synthetase A proteins were purified from 50 l batches of bacteria as described by Henning et al. (1962) as far as the chromatography on G 100 Sephadex. All buffers contained 10^{-3} M-\beta-mercaptoethanol and 10^{-3} M-EDTA. The precipitated fractions from the G 100 Sephadex column were resuspended in the minimal volume of 0.1 M-potassium phosphate buffer, pH 7.2. After centrifuging at 38000 g for 10 min to remove solids, the supernatant was applied to a 100 x 2 cm diam. column of DEAE-Sephadex, equilibrated with 0.03 M-potassium phosphate buffer, pH 7.2. A linear gradient of 0.03 M to 0.3 M-potassium phosphate (700 ml in each vessel) was applied at a flow rate of 20 ml/h, and 12 ml fractions were collected. The peak fractions from this column usually have a specific activity of 2500 to 3500 u/mg protein. Protein from the pooled peak fractions was precipitated with 0.43 g (NH_4)_2SO_4/ml. The precipitate was collected by centrifugation at 38000 g for 20 min, resuspended in 0.1 M-potassium phosphate, pH 7.0, and dialysed for 2 h against 0.05 M-potassium phosphate, pH 7.0. After removal of insoluble material by centrifugation at 38000 g for 10 min, the protein was rechromatographed on a Sephadex G 100 column, 80 x 2 cm, at a flow rate of 20 ml/h; 5 ml fractions were collected. The peak fractions from the Sephadex column were precipitated with 0.43 g (NH_4)_2SO_4/ml. The protein pelleted after centrifugation at 38000 g for 20 min, was resuspended in 0.1 M-potassium phosphate, pH 7.0, and again chromatographed on a column of DEAE-Sephadex, 100 x 2 cm, at a flow rate of 15 ml/h; 5 ml fractions were collected. Specific activities in the peak fractions were usually about 4800 u/mg at this stage.

RESULTS

Recovery of frameshift mutants from a pseudowild revertant strain

Escherichia coli strain trpA46^{osp}PR3FR7, though phenotypically indistinguishable from wild-type, contains two frameshift mutations of opposite phase, between which are two missense mutations in adjacent bases (Berger, Brammar & Yanofsky, 1968). The pertinent amino acid and RNA codon sequences are shown in Fig. 1. An attempt was made to separate the two frameshift mutations by recombination in a genetic cross between A46^{osp}PR3FR7 and a trp^{+} wild-type strain. A PI-lysate grown on A46^{osp}PR3FR7 was used to transduce a cysBtrp^{+} recipient to cys^{+}, and the resulting cys^{+} transductants were screened for the presence of trp recombinants following a penicillin enrichment procedure as described in Methods.

Tryptophan auxotrophs recovered in this way fell into two phenotypic classes (Table 1). Some were able to grow very slowly on minimal agar, while others failed to grow. Mutants of both classes appeared to be frameshifts, since they were stimulated to revert by ICR 191, a powerful frameshift mutagen, but not by NTG, which is known to stimulate largely base replacements (Whitfield, Martin & Ames, 1966). Mutants of both classes fail to grow on plates containing 2 \mu g/ml indole + 100 \mu g/ml 5-methyl-DL-tryptophan (Brammar, Berger & Yanofsky, 1967), and show no detectable A protein activity in the conversion of indole to tryptophan (Crawford & Yanofsky, 1958). Their behaviour in both of these tests is characteristic of immunologically non-crossreacting (CRM^{-}) A gene mutants, and is therefore consistent with their classification as frameshift mutants.

To verify that the mutants isolated were derived by recombination from A46^{osp}PR3FR7,

and were not merely spontaneous tryptophan auxotrophs selected by penicillin enrichment, their map locations were investigated by P<sub>t</sub> transduction. Mutants of both classes showed very close linkage to trpA<sub>23</sub>, a missense mutant affecting the same codon as A46<sup>aS</sup> (Helinski & Yanofsky, 1962; Berger & Yanofsky, 1967). WBII11, the 'leaky' mutant, showed 0.06% recombination with A23, suggesting a separation of three to four codons (Yanofsky, Drapeau, Guest & Carlton, 1967), while the non-leaky mutant WB1 showed no detectable recombination with A23 (Table 2). A cross between the phenotypically different auxotrophs yielded trp<sup>+</sup> recombinants at a rate of 0.17%. Allowing for the fact that this figure includes both wild and pseudowild recombinants, such a recombination frequency suggests a separation between the two mutants of about six codons.

* In crosses with his/cys A23 as recipient, his is used as the reference marker: Cys\textsuperscript{+}, Trp\textsuperscript{+} transductants are selected to avoid a high background due to reversion of the trp marker.

\dagger When a cys/trp recipient is used, cys is used as the reference marker. Trp\textsuperscript{+}/Cys\textsuperscript{+} transductants were selected on plates containing 0.1 \mu g/ml 5-methyl-DL-tryptophan to prevent the growth of leaky mutants WB1I and A46\textsuperscript{+/}/PR3.

The genetic data are thus in excellent agreement with the expected behaviour of mutants derived by recombination of A46\textsuperscript{+/}/PR3/FR7 with wild-type. They would also suggest that the non-leaky mutant WB1 contains both the A46\textsuperscript{+/} missense mutation and a frameshift since it fails to recombine with A23. The leaky mutant WB1I is probably the base-addition frameshift mutation, since it fails to recombine with A46\textsuperscript{+/}/PR3, but does recombine with A23 (Table 2). The ancestral strain A46\textsuperscript{+/}/PR3, which contains both the A46\textsuperscript{+/} mutation and the base addition, is distinguishable from the leaky isolate WB1I by its slightly better growth on minimal agar (Table 1).

If the two classes of mutant recovered from A46\textsuperscript{+/}/PR3/FR7 are complementary frameshifts, then one or other must be of opposite phase to any other frameshift mutant. Thus it should be possible to produce pseudowild recombinants with a third closely linked frameshift mutant, provided the amino acid sequence generated by the altered reading frame between the two mutations is functionally acceptable. Mutant trpA21 contains a frameshift mutation of undefined phase located closely distal to the region defined by the two frameshift mutations in trpA46\textsuperscript{+/}/PR3/FR7 (see Fig. 2) (Berger et al. 1968). WB1I and WB1 were therefore crossed with trpA21, and trp\textsuperscript{+} recombinants were selected. On subsequent purification and characterization, the WB1I/A21 recombinants proved to be of two easily distinguished phenotypes; a fast-growing wild-type strain and a slower-growing pseudowild-type (WB138). In contrast, WB1/A21 recombinants were all phenotypically indistinguishable from wild-type. The pseudowild recombinants produced a CRM\textsuperscript{+} A protein with normal activity in the indole → tryptophan reaction (Table 1), and were presumed to contain frameshifts of opposite phase, derived from WB1I and trpA21. If this were the case, the codon sequence of the pseudowild recombinant would contain an in-phase tryptophan codon (UGG) generated from the third nucleotide of the phe\textsubscript{211} codon (UUU) and the first two nucleotides of the gly\textsubscript{212} codon (GGG) (see Fig. 2). Thus, the partially active A protein from the pseudowild recombinant WB138 should contain a single tryptophan residue.

To test this prediction, the tryptophan synthetase A proteins from the WB138 recombinant and the wild-type parent strain were extensively purified as described in Methods and their tryptophan contents were assayed in two different ways. The first method employed the formula of Goodwin & Morton (1946) to calculate the tryptophan and tyrosine contents directly from the u.v. absorption spectra in 0.1 M-sodium hydroxide. This method (Table 3) gave close to 1 mole of tryptophan/mole of the mutant A protein, while giving a suitably low value for the tryptophan content of the wild-type protein. The tyrosine content of the wild-type protein determined this way agreed well with the known value of 7 residues/mole (Yanofsky et al. 1967; Guest, Drapeau, Carlton & Yanofsky, 1967).

The tryptophan content of the mutant enzyme was also determined by following the oxidative cleavage of carboxyl-tryptophanyl peptide bonds by N-bromosuccinimide spectrophotometrically at 280 nm (Patchornik, Lawson, Gross & Witkop, 1960). This method gave a value of 0.86 residues/mole for the mutant A protein, while showing no detectable tryptophan in the wild-type enzyme. The method was checked using lysozyme, bovine serine albumin and pancreatic ribonuclease, and in each case values obtained agreed very well with those from the literature (Table 4). Thus these determinations of the tryptophan content of the mutant A protein confirm the prediction that the protein contains a single residue of tryptophan.

A gene expression in the mutant trpA138. The recombinant strain WB138 is itself leaky for tryptophan biosynthesis. Thus, in order to study the expression of the mutant A gene during tryptophan starvation it was necessary to introduce into the strain a complete genetic block on tryptophan synthesis. This was achieved by constructing a double mutant containing trpET3, a non-leaky missense mutant in the operator proximal E gene, together with the WB138 mutation. The expression of the A gene of this double mutant was compared with that of a trpET3A+ transductant isolated from the same genetic cross.

The specific activities of tryptophan synthetase A and B proteins were followed over 40 h...
Trp A gene expression

Fig. 3. The effect of tryptophan starvation on the synthesis of tryptophane synthetase A protein in trpA⁺ and wb138 strains. Both strains carried the trp⁻ missense mutant, trpET3. Cultures were grown in minimal medium containing 0·05 % (w/v) acid-hydrolysed casein, 0·3 % (w/v) glucose and a growth-limiting concentration of L-tryptophan (4 µg/ml). Samples were harvested when growth stopped due to depletion of tryptophan (time 0), and at intervals for a further 36 h. The data are plotted as the ratio of A protein activity to B protein activity to emphasise the differential synthesis of A protein. ○ — — ○, trpET3, wb138; ● — — ●, trpET3, A⁺.

Table 4. Tryptophan contents determined by titration with N-bromosuccinimide

Samples (2 mg) of each protein were dissolved in 1·3 ml 8 M-urea, adjusted to pH 4·0 with glacial acetic acid. Samples were titrated by addition of 10 µl samples of 10 mM-N-bromosuccinimide, and the decrease in absorption at 280 nm was followed. The calculations of the tryptophan contents were based on the following molecular weights: Lysozyme, 15000 (a); bovine serum albumin, 65000 (b); pancreatic ribonuclease, 14800 (c); tryptophan synthetase A protein, 29500 (d).

in the absence of tryptophan. The data, expressed as the ratio of A protein to B protein, are shown in Fig. 3. It is evident that the preferential synthesis of A protein observed with the trpA⁺ strain, and with all other A gene mutants examined, is eliminated in the strain which has a tryptophan residue in its A protein.
DISCUSSION

The frameshift event which gave rise to \( A_{46}^{ag}PR3 \) created a tryptophan codon in the wild-type reading frame. The tryptophan synthetase A protein from \( A_{46}^{ag}PR3 \), although feebly active in vivo, could not be detected or analysed in vitro (Berger et al. 1968). Unfortunately, the mutational event which gave rise to the pseudowild revertant \( A_{46}^{ag}PR3FR7 \) eliminated the \( trp \) codon and created a \( cys \) codon in restoring the wild-type reading frame. By separating and recovering the component frameshift mutants from \( A_{46}^{ag}PR3FR7 \), and then recombining one of them with another, more distal frameshift mutant (A21), it has been possible to create a double mutant which contains a \( trp \) codon in its A gene.

The nature of the u.v.-induced mutational event in \( trpA21 \) had not previously been precisely defined: it could have been a deletion of either one or two nucleotides (Berger, Brammar & Yanofsky, 1969). Because A21 is complementary in phase to the single nucleotide addition in \( A_{46}^{ag}PR3 \), the mutational event in A21 must be a single nucleotide deletion.

In principle, it should be possible to recombine \( A_{46}^{ag}PR3 \) itself with A21 to generate a multiple mutant and restore the wild-type reading frame. In practice, however, this would be very difficult to achieve, because \( A_{46}^{ag}PR3 \) itself grows relatively well on minimal medium. It is interesting that \( A_{46}^{ag}PR3 \), which contains a frameshift mutation and two base-change mutations, grows very much better than WBII, which has only the frameshift event. This must be because the \( A_{46}^{ag}PR3 \) protein retains the wild-type phe residue at position 211, whereas in the WBII protein it must be replaced by an ile residue.

One of the two frameshift mutants isolated, WBII, shows a significant reversion response with the alkylating mutagen NTG (see Table 1). NTG has been previously observed to stimulate the reversion of some frameshift mutations (Yourno & Heath, 1969), and it has been postulated that it does so by causing deletions of single base-pairs (Oeschger & Hartman, 1970). The NTG-stimulated reversion of WBII is not necessarily due to frameshift mutagenesis, however, since WBII could give rise to partial revertants like \( A_{46}^{ag}PR3 \) by base-change mutations.

The purified tryptophan synthetase A protein from the recombinant strain WB138 was shown to contain 1 residue of tryptophan/mole of protein, both from its spectrum and by titration with \( N \)-bromosuccinimide. Control experiments with the wild-type enzyme and with three other proteins demonstrate the validity of the methods. These determinations could be criticized on the grounds that the protein preparations were not pure. The preparation of mutant A protein used for these determinations had a specific activity of 4000 u./mg, suggesting a purity of about 80%. Care was taken to use a wild-type fraction with a similar specific activity. Since the two enzymes were purified by the same method it is probable that the two preparations contained the same impurities, and that the determined difference in tryptophan content is a real one. This conclusion is supported by inspection of peptide maps of tryptic digests of the two A proteins. The relevant wild-type peptide, TP 3, (Guest, Carlton & Yanofsky, 1967) is missing from the peptide map of the mutant protein, but a new peptide is evident which shows the u.v. fluorescence characteristic of tryptophan-containing peptides (unpublished results).

The preferential synthesis of tryptophan synthetase A protein during tryptophan starvation is eliminated in the strain which contains a tryptophan codon in its \( trpA \) gene. This result directly confirms the suggestion that the preferential synthesis of A protein is due to the latter's lack of tryptophan. Since Morse, Mosteller & Yanofsky (1969) have shown that tryptophan messenger RNA synthesis is normal during acute tryptophan starvation, the synthesis of A protein under these conditions must be due to independent translation of the
A gene region of messenger RNA. During tryptophan starvation ribosomes prior to a tryptophan codon would be arrested at the preceding codon (Capecchi, 1967; Bretscher, 1968a). Thus the ribosomes which translate the A gene messenger RNA must do so by internal attachment to the messenger RNA, at or near the beginning of the A gene region. The conclusion that ribosomes can attach to internal positions in a messenger RNA molecule has already been obtained by several different methods (e.g. Lodish, 1968; Spahr & Gesteland, 1968; Bretscher, 1968b; Morse et al. 1969; Webster & Zinder, 1969). It is not yet clear whether there is a specially coded ribosome-attachment site at the beginning of each gene, or whether a single initiation codon (AUG) will suffice.

It might be expected that acute starvation for a particular amino acid, in blocking ribosome movement, would act like a nonsense mutation and produce strong polarity. Morse & Guertin (1971) have recently shown, however, that amino acid deprivation very effectively relieves polarity in Escherichia coli by a mechanism which involves stabilization of the unprotected messenger RNA.

The absolute rate of A-protein synthesis during prolonged tryptophan starvation is of interest. In these experiments the specific activity of wild-type A protein increased from 25 u/mg protein at 6 h to 73 u/mg after 24 h of starvation. This represents an increase of 48 u/mg in 18 h (or 2.7 u/mg/h), which corresponds to the synthesis of about 1350 molecules of tryptophan synthetase/organism/h. On derepression with indole propionic acid, a log-phase culture of the w3110 strain synthesizes about 12000 molecules/organism/h (Morse, Baker & Yanofsky, 1968). Thus, under conditions in which the synthesis of other proteins has stopped due to lack of tryptophan, tryptophan synthetase A protein is synthesized at about 10% of its maximum rate.

I am indebted to Dr R. P. Ambler for helpful advice, to Drs C. Yanofsky and H. Berger for bacterial strains, and to Susanna Winton for valuable technical assistance.
