INTRODUCTION

The iron transport system of Mycobacterium smegmatis involves the participation of at least two iron-binding molecules. The first, mycobactin, which is lipid-soluble, transports iron through the boundary layers of the bacterium (Ratledge & Marshall, 1972). As mycobactin is not secreted into the medium, a second compound has to be produced to solubilize the iron, which otherwise might not come into contact with the bacteria. Although we had previously supposed that salicylate, which is found almost exclusively in the medium (Ratledge & Winder, 1962), functions as this external iron scavenger, we have recently shown that its capabilities for this role are limited. In the presence of phosphate, as for example in a basal-salts growth medium, salicylic acid fails to hold iron in solution at physiological pH values (Ratledge et al. 1974). Its function as an iron chelator under such circumstances has therefore been discounted. However, a specific and unrestricted role for salicylate may be to transfer reduced iron (i.e. Fe$^{2+}$) from mycobactin, after its transport to the inner surfaces of the bacterial envelope, to an acceptor molecule such as porphyrin (Brown & Ratledge, 1975).

This preliminary report describes investigations undertaken to resolve the problem of how M. smegmatis solubilizes iron in phosphate-containing medium and the detection of a novel series of water-soluble, iron-binding compounds which, because of their chelating ability and occurrence in the growth medium, have been given the trivial name exochelins.

METHODS

Organisms and growth. Mycobacterium smegmatis NCIB8548 and M. bovis var. BCG were grown as previously described (Ratledge & Marshall, 1972), either in shaken 250 ml conical flasks containing 100 ml medium, or in a vortex-aerated fermenter holding 600 ml medium. For iron-deficient growth Fe$^{2+}$ was at 0.05 μg/ml and for iron-sufficient growth it was at 2.0 μg/ml.

Estimation of iron-solubilizing compounds in media. Samples (about 5 ml) of growth culture medium were taken at various times and the bacteria removed by filtration through membrane filters (0.45 μm pores). To a 1.0 ml portion of the filtrate was added 0.1 ml $^{55}$FeCl$_3$ solution (10 μg Fe$^{2+}$; 45 nCi $^{55}$Fe) in 0.1 M-HCl. The mixture, with a pH of about 6.7, was allowed to stand for 3 h, then 1.0 ml was dialysed through Visking tubing against 10 ml uninoculated growth medium for 20 h at 20 °C. Samples (0.5 ml) of the dialysate were then taken for radioactive counting. Aqueous samples containing $^{55}$Fe were counted by liquid scintillation as previously described (Ratledge et al. 1974). Standard solutions of $^{55}$Fe were used to calculate the actual amounts of iron.

Isolation of exochelin. Iron-deficient medium (1 to 2 l) from three-day-old cultures of
Short communication

*M. smegmatis* was filtered through Whatman GF/A paper. Solid FeCl$_3$ was added in 2 to 3 mg portions until the formation of orange colour was complete and addition of further FeCl$_3$ resulted in a precipitate. The pH was adjusted if necessary to between 6·8 and 7·2. The medium was left to stand at 3°C overnight, then the excess iron was filtered off by passage through GF/C paper. The extinction at 430 nm of such medium was between 0·3 and 0·5, whereas the corresponding extinction of filtered medium to which no iron had been added was usually 0·03 to 0·05.

Ferri-exochelin was isolated from the medium by adjusting the pH to 3·5 with HCl. The solution was passed through a 7×3 cm column of Zerolit 225 (SRC 10) sulphonic acid-type ion-exchange resin at about 10 ml/min. The column was washed with about 100 ml water and the exochelin then eluted with 1 M aqueous NH$_3$ at about 2 ml/min, which immediately after collection was rotary evaporated under vacuum to dryness.

RESULTS

Production of iron-solubilizing agents in the medium during growth of mycobacteria

Culture filtrates of *M. bovis BCG* and *M. smegmatis* were examined for iron-solubilizing agents. To maximize formation of any such compounds, the bacteria were grown under iron-deficient conditions. The existence of a compound, or compounds, capable of holding iron in such solutions (determined as dialysable $^{55}$Fe) at a pH near neutrality was confirmed for both organisms (Table 1). The test procedure did not detect any dialysable (i.e. soluble) iron in the uninoculated growth medium. The capacity of *M. smegmatis* culture filtrates to hold iron in solution increased progressively until 5 days’ growth, when effectively all the iron added in the test (10 μg/ml culture filtrate) was solubilized. Filtrates from cultures of this organism grown under iron-sufficient conditions did not possess such a high capacity for solubilizing iron, although low concentrations of iron were solubilized after three days’ growth.

Table 1. Capacity of mycobacterial growth media to solubilize iron

Culture medium (1 ml) was mixed with 10 μg $^{55}$FeCl$_3$ and then dialysed against fresh growth medium (see Methods). Samples of the dialysate were counted and the concentration of iron calculated from appropriate standard solutions of $^{55}$Fe. Both organisms were grown in shake-culture: *M. smegmatis* was fully grown after 5 days, *M. bovis* was almost at the end of growth by 7 days.

ND, Not determined.
The nature of the iron-solubilizing compound(s)

The compounds in culture filtrates of *M. bovis* BCG have not yet been examined in detail but preliminary work has shown them to be distinct from the exochelins from *M. smegmatis*; unlike the compounds from *M. smegmatis*, they are freely soluble in organic solvents and can be extracted from aqueous media into chloroform. The remainder of this report is devoted to the material isolated from *M. smegmatis*.

When FeCl₃ was added to the culture filtrates of *M. smegmatis* grown under iron-deficient conditions, an orange, dialysable compound was formed. The material or its desferri counterpart could not be extracted at pH 7 or pH 2 into organic solvents such as diethyl ether or ethyl acetate. It also failed to partition into n-butanol or phenol-chloroform (1:1, w/v) mixture. When isolated after ion-exchange chromatography and evaporated to dryness, the ferri-complex was only sparingly soluble in methanol or ethanol but readily re-dissolved in water to give a deep red solution. A sample of the partially purified ferri-containing material showed no u.v. absorption or fluorescence, confirming that it was not a phenolic or aromatic acid and therefore unrelated to salicylic acid which had previously been conjectured as the external iron-binding compound. The material does not correspond to any of the previously recognized microbial water-soluble iron-binding compounds (Lankford, 1973; Neilands, 1974).

The visible spectrum of ferri-exochelin showed a single broad peak at 430 nm which was unchanged both in wavelength and extinction between pH values 2.5 and 9.3. Beyond these pH values, simple decolorization took place without a spectral shift to 510 nm which is characteristic of simple ferric hydroxamate (Neilands, 1967). Ferri-exochelin is a basic compound and, by electrophoresis, has a probable pI of 9.3. It was readily reduced in aqueous solution by adding Na₂S₂O₄. Fe²⁺ could be removed from the resulting solution by adding bathophenanthroline and subsequently extracting into chloroform. The desferri-exochelin solution was a very pale straw colour. Alternatively, iron could be slowly leached from ferri-exochelin by allowing solutions of it to stand for 24 h in contact with 50 mM-EDTA or 5 mM-8-hydroxyquinoline.

**DISCUSSION**

Most micro-organisms have the ability to solubilize iron which, because of its insoluble nature, otherwise may never come into direct contact with the cells. This process is mediated by the secretion of iron-binding compounds which have been described in several organisms (Lankford, 1973; Neilands, 1974). In mycobacteria, salicylic acid was originally thought to fulfil this role but the formation of Fe³⁺(salicylate)₄ could not be demonstrated in the culture medium, principally because of competing phosphate ions (Ratledge et al. 1974). Mycobactin has been shown to be unable to solubilize precipitated iron from aqueous media (Ratledge et al. 1974). From the work described here, iron solubilization is achieved by compounds termed exochelins which, at least in *M. smegmatis*, are structurally unrelated to salicylic acid.

However, exochelin must be able to give up the iron it has solubilized to the bacteria, and this aspect of its function has been demonstrated using purified exochelin from *M. smegmatis*. We followed the uptake of ⁵⁵Fe, either as ⁵⁵FeCl₃ or ⁵⁵Fe-exochelin (prepared by mixing ⁵⁵FeCl₃ with desferri-exochelin), into washed, iron-deficient bacteria suspended in 0.1 M-phosphate buffer (see Ratledge et al. 1974). The initial rate of incorporation of iron into the bacteria was three times faster from exochelin than from ⁵⁵FeCl₃; the rate of uptake was
Short communication

about 50 ng Fe/min, a rate comparable to that reported previously for iron uptake into growing bacteria (Ratledge & Marshall, 1972).

These exochelins undoubtedly fall within the broad classification of iron-binding compounds termed siderochromes (Keller-Schierlein, Prelog & Zahner, 1964). Preliminary examination of the exochelin from M. smegmatis showed that it was a mixture of closely-related compounds. The major component appeared to be a cyclic hexapeptide containing 3 mol εN-actyl-εN-hydroxylysine (Macham, unpublished work). There may be some functional relationship between the exochelins and the red-brown ferrioxamines which have been isolated from several actinomycetes (Prelog, 1963) including a species described as a nocardia (Keller-Schierlein & Prelog, 1961). However, the ferrioxamines do not contain εN-hydroxylysine. We thus conclude that exochelins represent a new series of water-soluble, iron-binding compounds.

Exochelins are secreted into the medium in increasing amounts when the mycobacteria are grown under iron-deficient conditions in common with iron-binding compounds of other micro-organisms (Lankford, 1973; Neilands, 1974). After scavenging what iron there may be available, exochelins are then able to transfer the iron directly to the bacterium. This process we imagine will be mediated through mycobactin and further work on the mechanism of iron transfer from exochelin to mycobactin is currently underway in this laboratory.

We thank the Science Research Council (U.K.) for the award of a grant (B/RG/2256) in support of this work and a postdoctoral fellowship for L.P.M. We are indebted to Mrs S. J. Dews for her technical assistance.
