(Received 11 August 1975; revised 14 October 1975)

SUMMARY

The growth characteristics of Candida albicans CMI45,348 have been examined under aerobic conditions in continuous culture. At different steady states the environment was controlled with respect to the concentrations of dissolved oxygen, carbon and nitrogen, the pH, and the temperature. Dry matter, substrate concentration, yield, specific oxygen uptake, specific carbon dioxide release and respiration quotient were examined as a function of the dilution rate. The morphology depended on the carbon source. Maltose produced a mycelial morphology, whereas with lactate a yeast culture was obtained. With fructose or glucose as a carbon source a mixed morphology of yeast, pseudo-mycelial and mycelial forms was produced. A large number of different growth conditions were examined in batch culture but a mixed morphology was always obtained.

INTRODUCTION

The reversible transition from a yeast habit of growth to a mycelial one is well documented for a number of fungi. For Candida albicans a large number of different conditions and media have been described for producing the yeast-to-mycelial transition (Romano, 1966; Bartnicki-Garcia & McMurrough, 1971). In most of these studies, however, a non-synthetic medium was used and mixed populations of yeast, mycelial and pseudo-mycelial forms were obtained. A defined medium for the production of mycelial and yeast forms has been described (Marriott, 1975) and Simonetti, Strippoli & Cassone (1974) described a simple method for the production of germ tubes.

Despite the importance of C. albicans as a human pathogen, there are few reported studies on the intermediary metabolism and growth characteristics of this organism (Chattaway et al., 1973; Ward & Nickerson, 1958). To determine the biochemical factors that decide whether C. albicans grows in a mycelial or yeast form it is necessary to use a system where different physiological growth states are readily reproduced and where large quantities of yeast and mycelial cells can be obtained. Previously, yeast and mycelial forms of C. albicans have been obtained in shake cultures, but the lack of reproducibility promoted the present study. The use of the chemostat satisfies two requirements: it provides an analytical system for the study of growth characteristics, and of large quantities of yeast and mycelial cells grown under reproducible conditions. This paper describes the production and growth characteristics of yeast and mycelial forms of C. albicans (CMI45,348).

METHODS

Reagents. All chemicals were analytical reagent grade. Enzyme substrates and other biological substances were obtained from the Sigma.

Organisms and culture conditions. The strain of Candida albicans used was CMI45,348,
obtained from the Commonwealth Mycological Institute, Surrey. Fungi were propagated on either Sabouraud dextrose agar or malt extract agar at 28 °C.

Two basic media were used. N-limiting medium contained (per litre): carbon source, 15 g; (NH₄)₂SO₄, 0.5 g; KH₂PO₄, 2.0 g; CaCl₂.2H₂O, 0.05 g; MgSO₄.7H₂O, 0.05 g; ZnSO₄.7H₂O, 1 mg; CuSO₄.5H₂O, 1 mg; FeSO₄.7H₂O, 0.01 g; biotin, 25 µg; final pH 5.2. C-limiting medium contained (per litre): carbon source, 10 g; (NH₄)₂SO₄, 2 g; KH₂PO₄, 2.0 g; CaCl₂.2H₂O, 0.05 g; MgSO₄.7H₂O, 0.05 g; ZnSO₄.7H₂O, 1 mg; CuSO₄.5H₂O, 1 mg; FeSO₄.7H₂O, 0.01 g; biotin, 25 µg; final pH 5.2.

Slants (8 g vials) of C. albicans were shaken with 5 ml of Tween 80 solution (500 p.p.m.). This produced a suspension containing approximately $5 \times 10^8$ cells which was used to inoculate the fermenter.

Shake culture experiments. To determine the growth characteristics of C. albicans CMI 45,348 in submerged culture, a 2 l Erlenmeyer flask containing 1 l C-limiting medium with glucose as carbon source, was inoculated with $5 \times 10^8$ cells and shaken on a gyratory shaker at 250 rev./min at 28 °C; this flask was modified with three vertical flutes to improve aeration.

The effects of different media on the morphology of C. albicans grown in submerged culture were examined as follows. Suspensions containing $10^8$ cells were added to 250 ml Erlenmeyer flasks containing 250 ml of the appropriate medium, and then shaken at 250 rev./min at 28 °C. After 24 h, the morphology was examined by phase-contrast microscopy.

Chemostat studies. The chemostat was designed and constructed in the School of Biotechnology, University of New South Wales, Kensington, Australia. It had a culture volume capacity of 1 l and was equipped with automatic recording and control of pH and temperature; mixing was achieved with a Vibromix (Chemap, Mannedorf, Switzerland). The organism was grown in either a nitrogen- [as (NH₄)₂SO₄] or carbon- [as glucose, lactate, succinate, fructose or maltose] limited medium. The organism could be maintained in steady-state growth at any pH between 2.0 and 8.0 in the medium described, by the addition of either 2 M-NaOH or 2 M-HCl. The temperature of growth, unless otherwise specified, was 30 ± 0.1 °C. The air flow and the stirrer were adjusted to provide a $P_{O₂}$ (determined by a Johnson-type steam-sterilizable oxygen electrode; Johnson, Borkowski & Engblom, 1964) between 5 and 90% saturation of oxygen. The culture was regarded as having attained a steady state following a change in operating conditions when it had grown for at least seven doubling times, or for at least two doubling times during which there was no change in the monitored parameters of growth, i.e. $E_{540}$, $P_{O₂}$ of the culture, $P_{CO₂}$ of the effluent gas (determined in a Lira model 303 infrared analyzer; Mine Safety Appliances Co. Ltd, Glasgow), or concentration of one of the substrates. Where a change in morphology occurred it took 12 or more doubling times for a steady state to be achieved.

Analytical methods. The fungal cell dry matter was determined from a sample by using a calibration curve of $E_{540}$ versus dry weight. Separate calibration curves for mycelial, pseudo-mycelial and yeast cells of C. albicans CMI 45,348 were required. Glucose concentrations were determined by the glucose oxidase method (Lloyd & Whelan, 1969). Maltose was determined with 3,5-dinitrosalicylic acid reagent (Pettersson & Porath, 1966). Lactate was estimated colorimetrically by the method of Barker (1957). The micro-Kjeldahl method was used for nitrogen estimation (Ballentine, 1957).

Oxygen uptake measurements. The oxygen uptake rates of freshly harvested cells were measured in a Clark-type oxygen electrode (Yellow Springs Instrument Co., Ohio, U.S.A.; electrode 5331). Where necessary the sample was diluted with spent medium obtained just before the oxygen uptake determination. A Thermox Oxygen Analyzer (Thermolab

Table 1. The effect of carbon source on the morphology of C. albicans CM145,348 grown in shake culture

Instruments, Inc., Pittsburgh, Pennsylvania, U.S.A.) was used for oxygen analysis in the gas stream towards the end of the study.

Metabolic quotients. The specific growth rate, \( \mu \), of the steady-state continuous culture is equal to the dilution rate, \( D \), and is expressed in units of reciprocal time (h\(^{-1}\)). The specific rate of substrate utilization (\( Q_{\text{substrate}} \)) was calculated as \( \mu(S_0 - S)/X \), where \( S_0 \) is the original substrate concentration in the feed solution (g/l), and \( S \) and \( X \) are the steady-state values of the substrate level in the culture (g/l) and fungal dry weight (g/l), respectively. The \( Q_{\text{substrate}} \) is therefore expressed as g substrate (g dry wt\(^{-1}\)) h\(^{-1}\). The specific oxygen uptake and specific carbon dioxide release are expressed as mmol gas (g dry wt\(^{-1}\)) h\(^{-1}\).

RESULTS

Shake culture experiments

We tested the effect of a variety of additives on the morphology of C. albicans CM145,348. This strain was chosen because it grew in a shake culture of glucose salts medium with a mixed mycelial, pseudo-mycelial (Morris, 1966) and yeast morphology. The growth characteristics of C. albicans CM145,348 grown on glucose in a shake flask are shown in Fig. 1.

Table 1 shows the effect of carbon source on the morphology of C. albicans. In shake flask
experiments using N-limiting medium with glucose as carbon source, the (NH₄)₂SO₄ concentration was varied from 0.1 to 4 g/l. At low concentrations of (NH₄)₂SO₄, pseudo-mycelial cells predominated after 24 h, but as the concentration of the (NH₄)₂SO₄ was increased there was a small increase in the proportion of yeast cells. Mardon, Balish & Phillips (1969) reported that ammonium salts as nitrogen source promoted yeast-like growth of a variant strain of C. albicans. Cysteine was added to C-limiting medium, with glucose as carbon source, at final concentrations of 1, 10, 50 and 100 mM. There was inhibition of growth at concentrations greater than 10 mM and in these cases the morphology was examined for up to 72 h of growth. The higher the concentration of cysteine the more yeast cells were present, although the actual number of yeast cells varied from experiment to experiment. Cysteine has been extensively used to suppress filamentous growth of C. albicans (Nickerson & Mankowski, 1953).

Using C-limiting medium, with glucose as the carbon source, the following compounds, at the final concentrations given, had no significant effect on the morphology: manganese (1 μM, 10 μM, 100 μM and 1 mM), methionine (10 mM, 100 mM), phenethyl alcohol (0.1 %). It has been reported that methionine stimulated filamentous growth of C. albicans (Mardon et al., 1969), while phenethyl alcohol and Mn²⁺ influence the morphology of Mucor species (Terenzi & Storck, 1968; Bartnicki-Garcia & Nickerson, 1962).

Several other media were tried at both 28 and 37 °C. These include: GGY (glucose, 10 g; glycine, 10 g; yeast extract, 1.0 g; distilled water 1 l) at final pH values of 5, 6, 7, 7.5 and 8; GGY plus 10 % serum; GGY plus 0.5 % inositol; soluble starch (0.5 %) in place of glucose in GGY; glutamine (0.1 %) in place of glycine in GGY; and Dulbecco's modified Eagle medium (Grand Island Biological Co., Schipol-East, The Netherlands). Glycine (Mardon et al., 1969), yeast extract (Yamaguichi, 1974), serum (Taschdjian, Burchall & Kozinn, 1960), and soluble starch (Nickerson & Mankowski, 1953) have been used to cause filamentous growth. Inositol (Brown & Hough, 1965) affects the morphology of Saccharomyces cervisiae, while temperature-dependent dimorphism of C. albicans has been reported with growth on tissue culture medium (Dabrowa et al., 1979) and on basal medium (Chattaway, Holmes & Barlow, 1968). No batch system was found which would produce a complete yeast or mycelial culture; there was always a mixed morphology of yeast, pseudo-mycelial and mycelial cells. All cultures were examined at 24, 48 and 72 h, but the age of the culture had very little effect on the morphology. A disturbing feature of these experiments was the lack of reproducibility, and this was a principal factor in promoting the chemostat studies.

The size of the inoculum appeared to affect the morphology; generally a small inoculum (<10⁷ cells) increased the mycelial content while an inoculum of 10⁸ cells or greater produced a higher proportion of yeast cells.

**Continuous culture studies**

In the chemostat, the morphology of C. albicans CMI45,348 depended on the carbon source. The morphology was not markedly affected by varying the pH or the dilution rate. For any particular carbon source the morphology was the same whether the system was limiting with respect to nitrogen or carbon. A mixed morphology was obtained with glucose, fructose and succinate. Steady states were obtained with μ values between 0.05 and 0.2, and maximum growth rates of 0.30, 0.22 and 0.18 were obtained for glucose, fructose and succinate, respectively.

With lactate as carbon source a yeast culture was obtained, while a mycelial morphology resulted from the use of maltose as a carbon source. When shake flasks with glucose as the carbon source were inoculated and incubated with either the mycelial culture resulting from

growth on maltose or the yeast culture resulting from growth on lactate, a mixed morphology, typical of growth on glucose, was obtained.

Cysteine was added to a steady-state glucose-limiting system (μ 0.1, pH 5.0, dry weight 2.2 g/l) at 8 h intervals for 48 h to a final concentration of 10 mM. At the end of this period the dry weight was 0.4 g/l but there was no change in morphology.

The growth characteristics of C. albicans CM145348 grown on maltose and lactate in continuous culture are summarized in Tables 2 and 3 and Fig. 2. The μ\(_{\text{max}}\) values of 0.34 (maltose) and 0.18 (lactate) were obtained using wash-out curves. Nickerson & Chung (1954) found that C. albicans ATCC10261 (which grew predominantly as a yeast form) and a filamentous mutant derived from this strain had similar growth rates in batch cultures on GGY medium. It is not valid, however, to compare these results with the present findings, in which the different morphological forms were obtained with different carbon sources in continuous culture.
Fig. 2. Growth and metabolism of \textit{C. albicans} \textsc{cm}145,348 in continuous culture. The culture conditions are described in the text. Steady-state values for (○) dry matter (\(X\)), (●) substrate concentration (\(S\)), and (□) respiration quotient (RQ) are shown as a function of the specific growth rate (\(\mu\)). (a) Growth on maltose; (b) growth on lactate.

Fig. 3. Effect of the specific growth rate (\(\mu\)) on the specific rate of substrate utilization \(Q_{\text{substrate}}\) of mycelial and yeast forms of \textit{C. albicans} \textsc{cm}145,348. \(Q_{\text{substrate}}\) values were determined from the relationship \(\mu/Y_s\). (a) Growth on maltose; (b) growth on lactate.

The energy-balance equation derived by Pirt (1965) for cell growth is:

\[
\frac{I}{Y_s} = \frac{m}{\mu} + \frac{I}{Y_s},
\]

where \(Y_{s/a}\) is the observed growth yield (g cells/g substrate); \(\mu\) is the specific growth rate (h\(^{-1}\)); \(m\) is the maintenance coefficient [g substrate (g cells)\(^{-1}\) h\(^{-1}\)] and \(Y_s\) is the true growth yield (g cells/g substrate). This equation can be rearranged to:

\[
Q_{\text{substrate}} = m + \frac{\mu}{Y_s},
\]

where \(Q_{\text{substrate}}\) is the specific rate of substrate utilization \(\mu/Y_{s/a}\) [g substrate g (dry wt\(^{-1}\)) h\(^{-1}\)]. Plots of \(Q_{\text{maltose}}\) versus \(\mu\) and of \(Q_{\text{lactate}}\) versus \(\mu\) are given in Fig. 3. Substrate maintenance coefficients of 0.015 and 0.020 were found for maltose and lactate respectively.
Yeast and mycelial forms of Candida albicans

Fig. 4. Effect of the specific growth rate (μ) on the specific oxygen uptake rate (Qₒ₂) of mycelial and yeast forms of C. albicans CM145348. Qₒ₂ values were determined as described in the text. (a) Growth on maltose; (b) growth on lactate.

These values can be compared with the values of 0.018 for Aspergillus nidulans grown aerobically on glucose-limited cultures at 30 °C (Carter et al., 1971) and 0.022 for Penicillium chrysogenum growing aerobically in a glucose-limited culture at 30 °C (Righelato et al., 1968).

From Fig. 3, true growth yields of 0.39 (maltose) and 0.25 (lactose) were obtained. These values are low when compared with values of 0.58 for glycerol-limited growth of Torulopsis utilis (Clegg & Light, 1971), 0.50 for glucose-limited growth of S. cerevisiae (von Meyenburg, 1969) and 0.51 for growth of Candida utilis on glucose (Johnson, 1969). However, growth yields of 0.45 for glucose-limited growth of P. chrysogenum (Righelato et al., 1968) and 0.38 for C. utilis grown on acetate (Johnson, 1969) have been observed.

Analogous to eqn (2), the specific respiration rate can be described in terms of maintenance and growth (Pirt, 1965):

\[ Qₒ₂ = mₒ + \frac{\mu}{Yₒₒ}, \]

where \( mₒ \) is the maintenance coefficient for respiration [mmol O₂ (g cells)⁻¹ h⁻¹] and \( Yₒₒ \) is the true growth yield for oxygen (g cells/mol O₂). From Fig. 4, oxygen maintenance coefficients (\( mₒ \)) of 1.65 and 1.35 were obtained for maltose and lactate. It is not clear why the \( mₒ \) values for C. albicans are so much higher than the \( mₒ \) values of 0.55 for A. nidulans (Carter et al., 1971), and 0.74 for P. chrysogenum (Righelato et al., 1968). However, the much larger values of 5.5 for Azotobacter vinelandii (Nagai & Aiba, 1972) and 3.4 for Aerobacter aerogenes (Herbert, 1958) have been reported.

**DISCUSSION**

Although there are many reports in the literature on how to induce the yeast–mycelial transformation in C. albicans we have had difficulty in obtaining a reproducible method using batch cultures, whereas a chemostat offered several advantages. The medium was a synthetic one, the conditions of growth were reproducible, and large supplies of cells could be obtained for biochemical assays. The observation that maltose favoured the production of mycelial forms supports the reports of Marriott (1975) and Nickerson & Mankowski (1953) that starch promotes mycelial production in batch cultures of C. albicans. Unlike Marriott, however, we did not find that phosphate affected the morphology; a chemostat run with glucose as a carbon source but with limiting phosphate gave a mixed morphology regardless of the dilution rate. A number of strains of C. albicans did not produce yeast and mycelial cells in the chemostat; for example C. albicans ATCC10261 formed yeast cells regardless of the carbon source.
An obvious difference in the lactate and maltose growth characteristics is the final pH of the culture. With lactate the pH of the medium increased to pH 8·0 (μ = 0·02) from the original value of pH 5·8 (Table 3), while with maltose the pH dropped to pH 2·7 with μ equal to 0·08 (Table 2). This drop in pH was found when C. albicans was grown on any sugar and was a characteristic feature of all strains of C. albicans tested.

With both lactate- and maltose-limited growth, the yield constant Y varied over a range of specific growth rates (Fig. 2). It is believed that the decrease in Y at low dilution rates is because endogenous metabolism becomes a higher proportion of the total metabolism (Mor & Fiechter, 1968). On approaching the critical dilution rate there is again a decrease in yield. This behaviour is typical of yeast cultures (Aiba, Humphrey & Millis, 1973) and shows that the assumption that the yield coefficient is independent of the specific growth rate is probably not valid. The rate of transfer of substrate carbon to yeast cells could be of importance in explaining this phenomenon.

That the maltose m₀ value was higher than the lactate m₀ value (1·65 as against 1·35) could be due in part to the energy requirement of the maltose culture in keeping the intracellular pH greater than the extracellular level of approximately 2·8 (Table 2). If this was so, however, it might be expected that the substrate maintenance coefficient for maltose would be larger than for lactate. The very large oxygen maintenance coefficient may be a reflexion of the nature of respiration for this organism. Firstly, the number of energy coupling sites in the mitochondria of C. albicans could be less than three. Secondly, there is present in C. albicans (unpublished results) the type of NADH shunt that exists in T. utilis (Light & Garland, 1971) which would utilize oxygen with a P/O ratio of 1. Finally, we have detected in C. albicans an active cyanide-insensitive respiration (Chin, Shepherd & Sullivan, 1975) which is present in both lactate and maltose cultures. Whether this alternative respiration has any function in the physiological state of C. albicans remains to be determined. The large oxygen maintenance coefficient observed for glucose-limited cultures of Azobacter vinelandii was explained in terms of uncoupled growth (Nagai & Aiba, 1972).

An interesting aspect of Tables 2 and 3 was that with both maltose and lactate the respiration quotient decreased with increasing specific growth rate. It would appear that the intermediary metabolism is influenced by the growth rate of the organism. One explanation for the decrease in respiration quotient would be that, as the growth rate increased, intermediary metabolites which are more oxidized than the substrate either accumulated or were used in biosynthetic pathways. As a consequence, the CO₂ evolved would decrease relative to the oxygen utilized. The decrease in respiration quotient with increasing growth rate also implies that the catabolism of maltose and lactate to CO₂ is less efficient at higher than at lower growth rates. Liener & Buchanan (1951) reported that S. cerevisiae is able to satisfy up to 5% of its carbon requirements by CO₂ assimilation, and Wang et al. (1956) proposed that up to 10% of the pyruvate originating from glucose was involved in CO₂ fixation. It could well be that as the growth rate increased the importance of CO₂ fixation reactions increased. It remains to be established whether there is any relationship between the change in respiration quotient with growth rate and the change in yield factor with growth rate. A decrease in respiration quotient with growth rate has also been observed with S. cerevisiae in continuous culture (Mor & Fiechter, 1968).

We are grateful to Mrs S. E. Latimer for technical assistance. This work was supported in part by a grant from the Medical Research Council of New Zealand.
