(Received 17 September 1976)

**INTRODUCTION**

The antibiotic polyoxin D specifically inhibits chitin synthase in fungi (Corbett, 1974). The development of sporophores of the basidiomycete *Coprinus cinereus* has been shown to require chitin synthase activity (Gooday, 1972; Gooday, de Rousset-Hall & Hunsley, 1976). These authors found that sporophore development of *C. cinereus* was inhibited by concentrations of polyoxin D similar to those which inhibited the activity of chitin synthase preparations in vitro.

The edible mushroom *Agaricus bisporus* (Lange) Imbach contains chitin in its cell walls (Kreger, 1954; Michalenko, Hohl & Rast, 1976). To determine if chitin synthase activity is involved in mycelial growth and fruit body expansion of *A. bisporus*, we have examined the effect of polyoxin D on these processes. We have also examined the effect of cycloheximide, a protein synthesis inhibitor.

**METHODS**

*Organism.* *Agaricus bisporus* strains d621 and d649 were used. These are of direct commercial origin.

*Assessment of inhibition of colony growth.* Cultures of *A. bisporus* strain d621 were inoculated on to malt agar plates (Wood, 1976). Polyoxin D was incorporated into the plates before inoculation by spreading 0.2 ml of sterile filtered solutions of polyoxin D on to the surface of the medium. Concentrations are expressed as those present in the agar. After inoculation the plates were incubated at 25 °C and colony diameters were measured at intervals. Ten replicate plates were measured for each treatment.

*Treatment of growing and excised sporophores.* Growing sporophores were treated by injecting sterile solutions of polyoxin D into the stipe base. Approximately 40 μl containing 200 μg polyoxin D was introduced into the sporophore. Alternatively, sporophores were harvested at about stage 2 of development (Hammond & Nichols, 1976) by cutting across the stipe approximately 1 cm below the velum. Measurements were made of the stipe length and cap diameter, using calipers. The sporophores were then placed with the cut stipe ends dipping into small beakers containing 2 ml of solutions of polyoxin D at 2, 20 or 100 μg ml⁻¹, cycloheximide at 100 μg ml⁻¹ or distilled water. The sporophores and beakers were kept in chambers at 90% relative humidity for 2 days. During this period all of the solution was imbibed. The sporophores were then removed and the cap and stipe were measured again.

*Chitin content.* The treated sporophores were separated into cap, lower stipe and upper stipe tissues. Samples of these were homogenized in distilled water. Duplicate samples of the homogenate were removed and dried to constant weight. Other samples of the homogenate were treated with 10% (w/v) NaOH at 100 °C for 30 min and centrifuged at 6000 g for 10 min. The pellets were treated with 2% (v/v) HCl at 20 °C for 1 h, centrifuged and then...
Short communication

treated with 10% (w/v) NaOH for 30 min. Centrifugation was repeated and the pellets were washed twice with distilled water. The final pellets were resuspended in 5 ml 6 M-HCl in ampoules. The ampoules were sealed and the samples were hydrolysed for 12 h at 100 °C. HCl was then removed by evaporation and the dried material was redissolved in distilled water. Samples of this solution were assayed for glucosamine using the procedure of Ride & Drysdale (1972). Glucosamine contents were assumed to be directly related to chitin contents.

Chemicals. Polyoxin D was kindly supplied by Dr S. Suzuki, Rikagaku Kenyusho, Japan. Cycloheximide was obtained from Sigma.

RESULTS AND DISCUSSION

Polyoxin D was inhibitory to mycelial growth of A. bisporus. Colony growth was completely inhibited at 1 μM and was approximately 50% inhibited at 0.1 μM but was not visibly affected at 0.01 μM. The lowest concentration examined that gave complete inhibition (1 μM) corresponded closely to values of 1.4 and 0.6 μM respectively obtained for the Kᵢ of polyoxin D on chitin synthase preparations from Neurospora crassa (Endo, Kakiki & Misato, 1970) and Mucor rouxii (Bartnicki-Garcia & Lippman, 1972). The value of K for chitin synthase from C. cinereus with polyoxin D was 3 μM (Gooday et al., 1976).

After harvest of the sporophore of A. bisporus, the stipe lengthens and the cap expands to expose the developing gills (Hammond & Nichols, 1975). Treatment with polyoxin D or cycloheximide reduced this expansion (Table 1); sporophores treated with antibiotics expanded only some 12 to 13% over 2 days. There was less inhibition of growth in the cap tissues; this may be due to incomplete translocation of the inhibitor into the cap tissue.

The sporophores used were of approximately 10 g fresh weight. Thus there was an overall concentration of polyoxin D of 38 μM in those sporophores treated with 2 ml of antibiotic solution at 100 μg ml⁻¹. Gooday (1972) showed that 10 μM-polyoxin D considerably diminished the growth of excised stipes of C. cinereus and 190 μM was completely inhibitory. Development of sporophores of A. bisporus was also partly inhibited by cycloheximide indicating that continuing protein synthesis is required for sporophore enlargement. In longitudinal sections of polyoxin D-treated sporophores, the tissue of the lower stipe and the pileus appeared unchanged, but the upper stipe regions had become very brown and soft (Fig. 1). It is known that maximum elongation occurs in the upper stipe region of A. bisporus (Bonner, Kane & Levey, 1956).

Gooday (1972) has suggested that the softening of C. cinereus stipes following polyoxin D treatment may be due to the uncoupling of wall synthesis and degradation thus allowing uncontrolled autolysis to proceed. Coprinus sporophores grow faster than those of A. bisporus and, unlike the sporophores of A. bisporus, they undergo extensive autolysis at the end of development (Iten & Matile, 1970). Thus the autolytic system of A. bisporus sporophores is probably less active which may account for the observed difference in tissue softening between the two species. Browning and softening of the upper stipe region was much less marked in cycloheximide-treated sporophores. This may be due either to the inhibition of synthesis of autolytic enzymes or to the persistence of chitin synthase activity.

Antibiotic treatment of sporophores attached to underlying mycelium was also inhibitory to their development. When polyoxin D was injected into very small sporophores of approximately 10 mm height, the whole sporophore browned and autolysed. Gill development was also considerably retarded by polyoxin D treatment and this tissue showed considerable autolysis. Basidiospore formation was inhibited by at least 50% by the treatments with 20 or 100 μg polyoxin D ml⁻¹.

Analysis of chitin levels showed that sporophores treated with polyoxin D and cyclo-

Cycloheximide had a lower chitin content than untreated sporophores (Table 2). Sporophores harvested at the same time and analysed immediately also had less chitin. Since no carbon source was supplied to the sporophores during the treatment, the net chitin synthesis which occurs during development of excised sporophores must derive from other cellular components. Polyoxin D-treated sporophores had less chitin than fresh sporophores analysed immediately. This may indicate that the antibiotic treatment caused some hydrolysis of chitin. This is consistent with the observation of autolysis in the upper stipe tissue; furthermore, it seems likely that the mechanism for cell wall growth in *A. bisporus* is similar to that in *C. cinereus* (Gooday et al., 1976). Cycloheximide-treated sporophores showed chitin levels similar to those in sporophores analysed while fresh. The results from cycloheximide-treated sporophores also show that protein synthesis is required for net chitin synthesis. It appears, therefore, that the growth of the mycelium and sporophore of *A. bisporus* requires an active chitin synthase, and that the enzyme has a similar affinity for polyoxin D to that of chitin synthase in other fungi.
